SYMPOSIUM ON SYPHILIS IN ITS ECONOMIC ASPECTS

HANDLING OF THE VENEREAL PROBLEM IN UNITED STATES ARMY IN THE PRESENT CRISIS*

WILLIAM ALLEN PUSEY, M.D.
Chairman, Committee on Venereal Diseases for the Surgeon-General of the Army
CHICAGO

If we could handle venereal diseases as we can other infectious diseases they would offer a relatively simple sanitary problem. We know all of the facts necessary for their sanitary control. We know their causes, their incubation periods, and their modes of transmission; and these facts so far as they are physical facts offer no practical obstacles to sanitary control. But for all that some sanitarians may say, the venereal diseases cannot be handled simply as a sanitary problem. No effective policy is practicable which would isolate them like measles or scarlet fever; or quarantine them like smallpox; or, even in the present state of sentiment, get them successfully reported. They involve factors peculiar to themselves—social, personal and moral factors that reach into the most insistent and secret impulses of life. These facts make the problem of their control extremely difficult; make it a social as well as a sanitary problem and, without question, the most complex and difficult of social problems.

The Army program has taken full cognizance of both phases of this problem. It can readily be seen that they require very different treatment, and that in coordinating the forces necessary to attack them in a practical campaign, there may be need for tact, judgment, tolerance and sympathetic cooperation. In this attempt the dangers are many of cross purposes, of exaggeration of the importance of one part of the program over the other, of irreconcilable conflicts between radicals on the two sides, especially of having the moral propaganda run away with the medical. We all know to what extremes the sexual moralist can go. How unpractical, how intolerant, how extravagant, even how unreasoning, if not scientifically dishonest, he can be. On the other hand, the medical man can make no boasts of the cool, dispassionate, scientific intelligence that he has brought to bear on the problem. He is usually an infant in the knowledge of the epidemiologic facts of the venereal diseases and of the work that has been done on them as a sanitary problem. If he does not content himself with a mild mistrust of social and moral propagandas for influencing their prevalence, he is apt to have opinions about what he fondly regards as the practical aspects of the sexual problem, which are not the less vigorous because he has given very little serious study to the subject.

A very practical proposition has been to avoid the danger of being carried away by extremes in policy in either direction. Up to the present time, however, this danger has not actually obtruded itself.

METHODS OF PREVENTION

All of the methods of attack on the venereal diseases may be grouped into four classes: (*a*) Social measures to diminish sexual temptation; (*b*) education in regard to venereal diseases; (*c*) prophylactic measures against venereal diseases, and (*d*) medical care.

SOCIAL MEASURES

Social measures to diminish sexual temptation divide themselves in two sorts of activities: (1) the repression of prostitution and of the liquor traffic, and (2) the provision of proper social surroundings and of opportunities for recreation and diversion.

However unjust it may seem to some, the repression of prostitution and of the liquor traffic are logically classed together. In the spread of venereal diseases they go together. The liquor traffic in numerous ways is the fosterer of prostitution. And the effect of alcoholic liquor is a factor that cannot be overlooked in the diffusion of venereal diseases, because of the inhibition which it produces in those restraining influences that under ordinary conditions prevent man's giving way to his impulses.

It has been recognized, then, by the Army that keeping liquor away from soldiers is of fundamental importance in the program of attack on the venereal diseases. It is not necessary to go into the measures which the government has enacted to keep alcoholic liquors away from the soldiers. It may be said, however, that these measures are being enforced, and that the amount of alcohol consumed by the present Army of the United States is negligible. There is an occasional bootlegger, and a small amount of liquor gets to the soldier in devious ways; but it is, in the total, inappreciable. For all practical purposes the United States Army at the present time is a body of total abstainers. This fact is undoubtedly a very great factor in keeping down in the Army the incidence of venereal diseases.

---

* Read before the Section on Dermatology at the Sixty-Ninth Annual Session of the American Medical Association, Chicago, June, 1918.

* Because of lack of space, this article is abbreviated in The Journal. The complete article appears in the Transactions of the Section and in the author's reprints.

The control of the liquor traffic and of prostitution has been one which has called for cooperation between federal and local authorities. Of course, inside cantonments and other government reservations the federal authorities are supreme. In addition to this federal area, a district has been provided by law, consisting of a zone, at present designated by the Secretary of War to be 5 miles, around each of the cantonments. In these zones the federal authorities are in position to control completely the liquor traffic and the various conditions which encourage prostitution. Even, therefore, where cantonments are situated near districts presenting the worst social conditions, the government is able to make prostitution difficult, and is very effectively doing it.

Outside the zones, the federal government can still exert great influence as regards these conditions, and, as necessity compels, is doing this. But for the most part, when it comes to the question of controlling prostitution and liquor traffic outside the zones, reliance has been placed in great measure on the local civil authorities. I think it can be said with considerable satisfaction that communities have almost without exception realized their responsibility in these matters and have responded as well as the most sanguine could have asked in their efforts to improve them. Cities have cleaned up in the last few months that have never cleaned up before; to such an extent is this true, that conditions in regard to prostitution in this country are the best today that they have ever been.

The cause of this is the awakened public conscience; the determination of our people to do the best they can for their soldiers. To attain this, much has been done in directing the public conscience, in discovering the conditions that need correcting, and in showing the public useful avenues of work.

In this ticklish business the Army is not trusting to well meaning amateurs alone. It has its own trained forces in the field, recruited largely from the experienced workers of such organizations as the American Social Hygiene Association. Vice conditions are minutely studied, and are known with a fulness that is surprising. Often, as a result of this, the condition of prostitution in a community has been revolutionized for the better almost in a day. More often the improvement is less magical. But the pressure is everywhere, most about camps, and is resulting in rapid betterment.

The interest of the intelligent public, not merely of the intellectual classes, but of the every-day citizen, in the menace of venereal diseases, has been accumulating in the last few years. The war has stimulated this to a point at which you can get the public to support any policy concerning them that is sane and useful. This makes the present time a unique opportunity for attacking the problem, and sanitarians are showing a disposition to utilize it. Everywhere the work for the control of venereal diseases is stimulated and many new approaches to the problem are being developed.

You can hardly find a district where there is not some manifestation of this activity. New and better ordinances and sanitary regulations in regard to venereal diseases are being enacted, and more intelligence is being applied to their enforcement. Municipal clinics for the treatment of venereal diseases are being established. Established clinics are being reorganized to do better work. Hospitals for venereal diseases are being provided; even, in some places, isolation hospitals for venereal cases are in operation. Evidence of this sort of activity is found everywhere from the Atlantic to the Pacific. There has never been any systematic widespread attack on venereal diseases in the country before. There is now an almost universal and, for the most part, intelligent attack carried on.

The state councils of defense have generally taken up the work in their various states. Private organizations interested in public welfare are helping the campaign in innumerable communities. The aggregate, therefore, of work which is being contributed by forces not directly controlled by the federal government is not easy to be estimated.

The second group of measures to diminish sexual temptation are embodied in the provision of proper social surroundings and recreations. Applied to the Army, this means the furnishing of healthy social conditions and of opportunities for diversion for the soldiers at periods of leisure in camp, or when they are traveling, or on leaves of absence outside of their camps. In the camps the government has through the Commission on Training Camp Activities pursued a policy which, it seems to me, is of the highest intelligence in regard to the provision of recreations. The situation has been conceived to be much the same as that of a college community, where there are a large number of young men brought together, who have recently been detached from their familiar home surroundings; and it has been handled with college activities as the example to be followed. All of the wholesome forms of play which constitute the familiar recreations of college life have been included, and are encouraged and supported. The effort is to create the same sort of a class spirit among the men; to get them interested in their diversions and to excite in them a pride in their sports as in their work.

In furnishing proper social surroundings and facilities for recreation in the camp, the authorities have availed themselves of the invaluable experience of organizations which have been working so long in these fields in civil life, such as the Y. M. C. A., the Knights of Columbus and the Y. W. C. A. These organizations are not only doing incalculable work for the soldier in the cities; they are doing a greater one in the camps, where they have adapted themselves to military conditions.

Outside the cantonments and the zones, there has been an appeal to the civil population to add their part in this work. I think you are all more or less familiar with the cordial response which the public has given to this appeal. Hardly a community (no community that I know of) has failed to respond to this appeal to aid. What some communities have done amounts to examples of almost illimitable hospitality.

EDUCATION

The same civil agencies that have been working against prostitution have been active in the campaign of education of the public in sexual matters and in the dangers of venereal diseases. Education as to the dangers of venereal diseases has been a part of the general campaign. While the work of education has not been as extensive among the civil population as it has been among the soldiers, it has been by the same methods; the aggregate amount of it is very large and is undoubtedly doing a very practical amount of good. Nor has this campaign of education in the danger of venereal diseases been confined to the boys. It has been extended to the girls; and such organizations as the Young Woman's Patriotic League are reaching out to the girls: telling them the danger of venereal diseases and fostering in them a sense of their responsibilities in these matters. The General Federation of Women's Clubs, the Women's Christian Temperance Union, the Y. W. C. A.—such women's organizations as these are giving their powerful support to this work.

When it comes to the soldiers, the work of education is systematic and so thorough that it reaches every man. All of the agencies that have been mentioned already are lending their cooperation in this work. The work is guided and largely done by the War Department Commission on Training Camp Activities and the Social Hygiene Section of the Surgeon-General's Office. Instruction is given by lectures, by pamphlets, and by exhibits and moving pictures. But reliance is not placed solely on measures of general instruction.

Lectures and exhibits and pamphlets for the soldiers in general serve a useful purpose, but they do not reach the soldier that is most in need of them. To reach the soldier in the way that is unfailing and that makes a real impression on him is through his company commanders—the men from whom he takes his orders, and to whom he naturally looks for guidance. Through this channel pamphlets are distributed to him that give safe and unsensational information. But much more telling than this, company officers, both line and medical, give lectures to their men on sexual matters and the danger of venereal diseases. Every soldier is instructed on this subject. This is not a matter left to the volition of the officer; it is a matter concerning which he is under orders and the performance of this duty is seen to by checking up as in other important matters.

It is a difficult thing to get a good popular lecture to young men on sexual matters. In one quarter we get the maudlin; in another the extravagant, sensational and untruthful; in another the unreasonable and impractical; and even when the lecturer is sane, and honest, and wants to tell the truth, it is hard to get actual knowledge of the subject, and harder still to put such a lecture into form. To overcome, as far as possible, these difficulties, company officers are provided with full lectures on these subjects which they can use as such or as a basis for lectures of their own.

The lectures on sexual hygiene and venereal diseases given by company officers to their men are not inane, pseudomoral stuff. They are plain, serious, instructive talks given by practical men. These lectures reach all of the men; the two million men now under arms for the United States have been instructed more systematically and probably more intelligently than any other large body of men have ever been instructed in sexual and venereal subjects. It is not making saints of them; but it is doing a great deal in saving them from venereal diseases.

SEGREGATION OF PROSTITUTES

It will doubtless be noticed that in this program for the repression of prostitution nothing has been said about segregation, and that no part of it includes either the examination or certification of prostitutes. In the program everything possible is tried to discourage prostitution. It is a part of the policy to stimulate activity in providing adequate care of venereal diseases among the civil population, to the end, for one reason, that the numbers of venereal disease "carriers" shall be reduced as much as possible. There has been a very noticeable access of energy in the public care of venereal diseases as a result of the whole program that we have been considering. But the segregation of prostitutes and the regulation of prostitution in the Continental sense, that is, the examination of prostitutes, their certification and their toleration in definite districts, have not been included in this program, because they have not been regarded as advantageous.

In the attempt to coordinate social and medical forces in an attack on venereal diseases there is danger that the social forces may be allowed to overshadow and to cause the neglect of proper medical measures. They are so appealing to the moral and religious ideals of human nature, while the medical side has no such call; and the moral propagandist is apt to be intolerant of practical considerations.

There is always the possible danger of an unreasoning propagandist trying to run away with the situation. The fears of this were well expressed by Colonel Lyster[1] of the Army in an article on venereal diseases and the war. He says:

> "Now as to our new Army and the future: Higher rates will probably prevail for some time, but hope is backed by knowledge that we have the means, if we can apply them, of controlling this great producer of nonefficiency in armies.
>
> "The greatest enemy to its [the Army's] health is venereal diseases. A continuation of the orders and methods successful in the Army from 1908 to date will make a successful answer to that challenge of disease. But no misleading and impractical fanatics must be permitted to have a hand in this question of national efficiency."

As far as I can sense the situation this danger has not yet materialized.

The two parts of the program have not proved unworkable together, and the forces behind the social program have not minimized the importance of or interfered with the effective administration of the medical program.

Medical Program

The second division of the program is the medical. The first part of this is prophylaxis to prevent infection after exposure. This, in the opinion of venereologists, is the crucial part of any program to reduce the prevalence of venereal diseases; omit it and you have omitted the most important single practical weapon we have for fighting this plague.

This part of the program is in universal effect in the Army and care is taken to see that it is thoroughly carried out. Venereal prophylaxis is a part of the duty of every regimental infirmary and of every other infirmary that has in its care the health of a unit of soldiers. The regimental infirmaries do most of this work and its conduct in the regimental infirmaries may be taken as an illustration of it in general. Everything for giving prophylactic treatment is always accessible in every regimental infirmary. The medical officers are responsible for it and it is carried out by specially trained noncommissioned officers. As far as possible selected men are chosen for these positions. I have inspected a good many regimental infirmaries and I have been impressed by the superior grade of these noncommissioned officers. Such an officer is constantly on duty and the returning soldier can get prophylactic treatment at any time in the twenty-four hours that he applies for it. This is a matter of general policy and is checked up by medical inspectors. It is seen to as far as possible that the conduct of prophylactic treatment is carried out seriously, without allowing an atmosphere of levity or obscenity to creep in.

---

[1] Lyster, William: Venereal Disease and the New Army, The Journal A. M. A., Oct. 13, 1917, p. 1257.

The necessity for medical prophylaxis is instilled into the soldiers' minds. They are universally told that it is not a sure preventive of infection; that the sooner it is applied the more likely it is to be effective; and that after eight hours it is likely to be ineffective. The taking of it, if exposed, is a matter of army regulation. If a man contracts venereal disease, he is not punished beyond losing his pay while the disease disables him for duty, provided he had prophylaxis after exposure. But if he contracts a venereal disease and has not, according to regulations, had prophylactic treatment, he is court-martialed for disobedience of orders and, if convicted, is punished.

Wherever I have been, there is invariable testimony to the value of medical prophylaxis. The number of cases of venereal infection that develops after prophylaxis is surprisingly small. I have visited several regiments where no such cases had developed since mobilization.

Among the measures which are regarded as prophylactic must be included two others; one is the loss of pay which, according to army regulations, disability from venereal disease entails; the other is the fortnightly physical inspections. Both of these, in force since 1912 (Lyster), are regarded by army authorities as very important measures in the reduction of venereal diseases.

MEDICAL CARE OF VENEREAL DISEASES

The second item in the medical program and the last item in the entire program is the medical care of those who are venereally infected. Necessarily the first step in putting into practical force the care of venereal diseases in the new Army was to obtain a group of competent specialists in their treatment. In going through the personnel of the medical reserve corps there was found a very considerable number of well trained specialists in genito-urinary, venereal and skin diseases. Among these were many of the best known men in the country in this field. The time of the great addition of soldiers to the Army was in September and October, when the National Guard and the National Army were mobilized in the thirty-one cantonments distributed over this country. Provision had suddenly to be made for the venereal care, as for the care of other diseases, of thirty-one cities, each containing a population of from 20,000 to 25,000 men between the ages of from 20 to 30 years.

It goes without saying that equally competent men were not obtainable for all these cantonments; but it can be said that at the time of the opening of each cantonment there was available in each, expert skill in venereal diseases. Since that time, as occasion has required, there have been added to the various camps whatever men trained in venereal diseases were asked for by commanding officers or necessity seemed to require. Necessarily there was confusion and lack of preparedness in material ways at the time of mobilization in the cantonments; for one cannot build thirty-one cities in three months and at the end of the time have them as complete and finished as though they had existed always. The men in charge of venereal diseases, however, for the most part have shown themselves equal to the situation and the exceptions are few in which those affected with venereal disease have not been able to get adequate care in the cantonment base hospitals.

In the planning of the base hospital of each cantonment, full provision has been made for venereal diseases. It is a part of the policy of the Surgeon-General that acute venereal disease shall be confined to the hospital until the acute infectious stages are past. This means that all cases of acute gonorrhea belong in the hospital and all cases of syphilis which have early active lesions.

It is difficult at times to get this policy carried out. In many divisions the division surgeon has seen the wisdom of this course and has taken his own initiative in putting it into force. In a few places it has been for a time impossible, because of epidemics of acute diseases which have had prior demands on all of the available hospital beds. The policy has been thoroughly promulgated by the Surgeon-General and attention is called to it wherever neglect of it is discovered. This is, in some respects, a new military policy with us. It is one which it is believed will justify itself. It has several arguments for it; one is the great advantage which it affords in gonorrhea of curing quickly and preventing its spread to the posterior urethra; another is the assurance which it gives of thorough early treatment of syphilis, and the rapidity with which the infectious stage is passed; a third, and a very great advantage, is the reduction in the danger of nonvenereal spread of these diseases.

An effort has been made to standardize as far as possible the handling of venereal diseases. The first item of this consists in the hospitalization of acute cases, which has been referred to. There has been no effort to hamper mature men in carrying out established methods of treatment, but their attention has been called to the fact that in the Army team work is desirable, that bizarre and original methods are not necessarily most effective, and that the methods recommended have borne the test of experience. In carrying out this policy a small manual of venereal disease has been issued which includes, in addition to the program of attack on venereal diseases, brief articles which represent present established methods of treatment of the various venereal diseases.

It is part of the program to provide in the base hospitals complete laboratory facilities for the care of venereal diseases. There is provided in each hospital a general laboratory in which Wassermann tests are to be made. It is also part of the Surgeon-General's policy that each venereal service in the base hospital shall have its own small laboratory, equipped for examination for spirochetes and bacteria and for urinalysis examination. These laboratory facilities exist now in most of the cantonments that I have visited; in some they have not been developed. But wherever it is found that they are lacking, their establishment is stimulated.

In addition to the cantonments, there are many other large camps in which the care of venereal dis-cases is handled on the same plans as has been outlined for the cantonments.

It is part of the program to use the specialists in venereal disease in the division as instructors of other medical officers in venereal diseases. As a rule, the chief of a venereal service in a base hospital is the chief officer in venereal diseases. He is expected to be an instructor of other medical officers and his efficiency is partly gaged, not alone by the care which he gives his patients, but by the efficiency with which he develops his hospital organization, and the way in which he takes part in handling the venereal problem in the cantonment as a whole.

In order to increase efficiency in venereal diseases, three schools have been established for the intensive training of the less experienced men who are in this work. These schools are conducted by well known specialists in genito-urinary diseases and syphilis and skin diseases and are in centers furnishing large clinical material. The instruction furnished by these schools along with the experience that is being gained by the men in the venereal service of the various cantonments and camps, is, to say the least, keeping the men in this work from stagnating. There is little room for doubt that, in most instances, it is increasing the knowledge of the junior officers rapidly. By this means, and by the constant addition of specialists from private life who are coming into the medical reserve corps, it seems safe to believe that, as the demands on this service increase, we will be able to meet them with competent men.

The policy of handling the venereal diseases that I have outlined is that of the Surgeon-General, and, as far as it depends on central authority, it is efficiency carried out. Of course, the success of the medical care of venereal diseases varies greatly in the different cantonments. The organization of the Army, properly I think, gives large discretion to the division commander and similarly to the chief medical officer, who is the division surgeon.

The conduct of medical affairs in the cantonments, therefore, depends to a very large extent on the attitude of those in supreme authority; that is, (1) the commanding general in a cantonment; (2) the division surgeon, and (3) the commanding officer of the base hospital.

If either one of the first two, and the same is true to a less extent of the third, should be obstinate, opinionated and ignorant, and interfere, he could spoil the best efforts of competent chiefs of service under him. I know of no instance where this has been so flagrant as I have just indicated as possible, but I think it is true that there is considerable variations in the efficiency of venereal services due to variations in these commanding officers. Nevertheless, the efficiency of the venereal service is, in very large part, what the chief medical officer assigned to the service makes it. Some of the men taken from civil life are showing great originality and efficiency in this service.

To mention only a few of those whose work I have seen:

Major William W. Townsend at Camp Dix has developed a clinic in the base hospital that meets the most exacting requirements of what such a clinic should be.

Major J. Bayard Clark at Camp Lee showed the same sort of originality before he was called to similar work overseas.

Capt. Victor N. Meddis at Camp Zachary Taylor has developed a highly efficient and well run service.

Capt. Charles M. Williams at Camp Meade has approached the work from another side and has developed an original and most efficient system of looking after venereal diseases throughout the cantonment from division headquarters.

I mention these especially because they illustrate the fact that there is room for the personal equation, for initiative and originality. The various intelligent plans which are developed are all useful additions to our experience in this work; and, partly on account of this fact, large latitude is given to the chiefs in the development of their services. The men previously mentioned undoubtedly could not have made such good showing without the support of their superior officers, but it is equally certain that with the same superior officers less efficient men would have made no such showing. One gains the impression, indeed, that in spite of so-called government red tape, military routine—which the civilian physician seems to regard in the way the public looks at medical etiquette—the equipment of the various hospitals, as well as their competency in other directions to take care of their patients, usually depends on the personnel of its medical officers. Sometimes it is impossible to get the necessary things, but as a rule you find the supplies ready for work in the place which is under the man who either knows how to get easily the things he needs, or is persistent enough to keep after these things until he obtains them, no matter how many obstacles he encounters in the endeavor.

QUALITY OF TREATMENT VENEREAL PATIENTS ARE RECEIVING

Venereal diseases are as a whole receiving excellent attention in the cantonment hospitals. Of course, the same factors of personal equation come in here, and the quality of service furnished in venereal diseases varies with the men who are furnishing it. But the men in charge of this work in the hospitals are trained specialists of long experience, and, without exception as far as my knowledge goes, are applying themselves with the utmost zeal and devotion to it. I have had a considerable opportunity to judge of the quality of treatment they are giving their patients and I believe it is as good as is to be obtained in any other forty hospitals in the United States.

The place where patients with chronic gonorrhea and syphilis are likely to fail to get expert care is in the division as distinguished from the base hospital. The regimental surgeon must be a general practitioner while he is in that position. Adequate care of syphilis and of the chronic complications of gonorrhea eminently demand expert training, and this is not any more to be expected of the regimental surgeon than is special training in all of the other specialties. He also cannot have the special equipment necessary for it. It follows, therefore, that gonorrhea and syphilis should as far as possible be taken out of the care of the general medical officers. It is the policy of the Surgeon-General to send them to the hospital as freely as practicable, and everything possible is done to encourage the return of ambulatory cases to the hospital for such treatment as they need. It is also the policy to have a qualified officer detailed to the special duty of supervising all venereal matters, including the treatment of venereal cases throughout the cantonment. But in spite of this, the fact remains that the weak point in the care of the soldiers' venereal diseases is the care he receives when he is on duty; and he is allowed to stay on duty often when it would ultimately be better for him and for the service, if he were nominally as well as actually sick and under expert care. This is often due to the attitude of the commanding line officer. He wants his men or he does not want them, and he has no use for the soldier who is taking half-days off to go to the hospital for treatment. There is room for much education here, and for the development of considerable more cooperation.

RESULTS

The venereal situation in the United States Army has been excellent for several years. This is the result of the effective policy in handling these diseases that has been developed by the medical department. The present situation in the Army, then, as far as it is favorable, is not the result of any new policy, but is due to the continuation of the Regular Army policy, with such additions as the new situations have seemed to indicate.

Of course, a marked increase in venereal diseases was feared in the present military situation. Such an increase always follows mobilization of new troops, and the conditions which this great increase in troops entail.

Between 1897 and 1900, which was the period that covered the Spanish-American War, the venereal rate went up from an average of 80 per thousand to 160.

As Colonel Lyster says of our new Army, "higher rates will probably prevail for some time."

In order to appreciate the situation now, it is worth while to consider the Army record for venereal diseases for several years past: The venereal rate of the Army previous to 1898 averaged about from 80 to 85 per thousand. This is no criterion on which to base the comparison with present rates, for then we had none of the present means of diagnosis, and much that is now recorded as syphilis at that time was not included. Colonel Lyster thinks under present conditions of recording syphilis, the rate for venereal diseases during that period would have been 110 per thousand or more. With the mobilization of new troops in the Spanish-American War in 1898 the rate suddenly doubled, going to 160 per thousand. The high rate then produced persisted after the War for thirteen years, varying between 180 and 160 per thousand until 1911. (The rates from 1905 until 1917, inclusive, are shown in the accompanying charts.) Between 1909 and 1911, an effective policy of handling venereal diseases in the Army was developed by the medical department. The most important features of this policy were the enactment of regulations which provided for loss of pay for disability from venereal diseases, weekly physical inspections, and venereal prophylaxis. The result of this policy was shown by the rapid and continuous decline in venereal diseases. From a rate of 164 per thousand in 1911, it dropped to 116 in 1912, and by 1913, in two years, it had dropped to 86.

There are few more signal feats in sanitation than the reduction of 50 per cent. in venereal diseases in the United States Army, which was brought about by the policy of handling them developed by the medical department. This feat is the more creditable because it was the result of an original policy largely developed in our own Army and Navy.

Since 1913, the rate has remained under 90, excepting during 1916. In 1916, as a result of the rapid increase of the Army and the mobilization on the Mexican border, the rate went to 91.4.

In my estimates, I have taken the rate of 90 as the mean average toward which we should strive in the present crisis, although the rate of 91 in 1916 would certainly be fairly justifiable as the standard.

The rate for the Regular Army from September, 1917, to May, 1918, averages a little better than 90.

With the second week of mobilization in September the venereal rate for the National Army shot up to 367 per thousand. The National Guard at this time showed a rate of 150. The Regular Army made a very strong showing for itself by presenting a rate of 80 on this particular date.

Much has been made of this enormous rate of venereal diseases at the mobilization of the National Army. As a matter of fact, it does not give any fair indication of the relative prevalence of venereal diseases in the three services, for this reason: When venereal disease is discovered for the first time in a soldier it goes on record and is counted as a new case. It may, however, be an old infection. The result is, when new recruits are received, all venereal diseases among them at once enter the records; they include old as well as new cases. But after these old cases have once been counted, only actual new cases get into the records as new cases. It takes, therefore, about four weeks before the actual incidence of new cases of venereal disease in a body of troops can be determined. It does, however, give one a very fair idea of the relative prevalence of venereal disease in different bodies of troops to compare the rate when first recorded for these different bodies. And in this respect the contrast between the figures for the National Army and for the National Guard are interesting. The rate for the National Army for the first four weeks after mobilization of the Army was twice that of the National Guard.

I believe it may be said that fact shows that venereal disease was at the time of mobilization twice as common among the men who went in the National Army as it was in the men in the National Guard. That difference probably indicated what the relatively lax discipline of the National Guard could do in holding down the venereal diseases as compared with conditions of civil life where restraints are very much less in force.

During the months of September, October and November new recruits were constantly coming in, but their numbers were rapidly decreasing. From the time of mobilization, the venereal rate in the National Army showed a remarkably rapid decline. On December 1, these rates crossed below the rate of 90. From December 1 to date the rate for the National Guard has not reached 90 per thousand.

The rate for the whole United States Army for 1917, in spite of the enormous peak caused by mobilization, is 88, as compared with 91.3 for 1916.

It is interesting also to see what has happened with our expeditionary forces in France among whom the same general policy of handling the venereal problem is in force.

Among these troops we have none of the sudden peaks in our rate that occur when new troops first get into the records, therefore we are able to obtain a fair idea of the normal rate of incidence of actual new cases of venereal diseases contracted while soldiers are in service. Since November 23, when the first report was published, to date for only two weeks has the venereal rate reached 90. The figures since December 21 are these: 75, 57, 74, 58, 52, 55, 44, 48. They are running pretty nearly one half of what we might have expected as a reasonable showing when the war began.

7 West Madison Street.

NEUROSYPHILIS

ITS DIAGNOSIS AND ECONOMIC IMPORTANCE*

JOHN A. FORDYCE, M.D.
Professor of Dermatology and Syphilology, Columbia University College of Physicians and Surgeons
NEW YORK

Neurosyphilis is a much more frequent sequence of the infection than is indicated by the available statistics which were compiled before the introduction of modern diagnostic methods. The older statistics took cognizance chiefly of the fully developed and classic types of tabes and paresis and failed entirely to recognize a large group of cases with indefinite nervous and mental symptoms often diagnosed as neurasthenia with nervous breakdown which existed for years before definite degeneration stigmata developed. The well known statistics of Mattauschek and Pilz are the most complete because of the long period covered. Taking the records of 4,134 cases of army officers who had been infected during the two decades between 1880-1900, these investigators followed their careers to the year 1911. They found that 4.75 per cent. had developed general paresis; 2.5 per cent. tabes, and about 3 per cent. cerebrospinal syphilis. Similarly Pilz made an independent study of prostitutes who had been under police control from 1885 to 1895. He collected 2,662 instances and was able to trace 643 patients in whom the infection had existed from ten to thirty-eight years. Of this number 1.32 per cent. had developed general paresis.

These figures, of course, are based mainly on the fully developed clinical symptomatology of neurosyphilis and probably did not take into account the large number of victims who belong to the same category from a laboratory standpoint but present only vaguely defined clinical signs difficult to interpret from a clinical study alone. I have in my case records many patients who have been passed on by physicians without a suspicion of the existence of syphilis until a cerebrospinal fluid examination revealed the true condition. It is impossible at this time to give accurate statistics as to the percentage of infected individuals who would show involvement of the fluid. We have, however, fairly accurate data as to the number of patients in the first year of the disease who show clinical and serologic evidence of such involvement. As a result of several years of observation, I am led to believe that once the fluid is infected with the *Spirochaetae pallidae* resulting in strongly positive reactions cure of such infection seldom occurs unless persistent and proper treatment is instituted and vigorously carried out. If we assume, therefore, that the 25 or 30 per cent. of patients who show abnormal fluids in the secondary stage retain the infection, they are potential candidates for one or the other forms of neurosyphilis. This would lead me to suspect that instead of 10 per cent. of syphilitics with nervous involvement according to the old statistics, at least 20 per cent. would, on careful examination, be shown. This conservative estimate is probably lower than the actual number that would be revealed by our modern methods of precision. It is possible, too, that later infection of the nervous system in uncured cases takes place from a focus in some part of the body as in tuberculous meningitis from a focus of that disease.

If the hypothesis that a normal blood and fluid after efficient early treatment insure such patients against neurosyphilis is true, a vast field is opened for prophylaxis of the really serious consequences of the infection. We can, at least by employing the newer methods of diagnosis and treatment, control the majority of the early infections of the fluid and greatly limit the number of neurosyphilitics in the future.

METHODS OF PREVENTION

The purely clinical methods of diagnosis employed in the past and unfortunately also at this time, together with inefficient therapeutic procedures, have resulted in a large number of individuals permanently disabled both mentally and physically who become inmates of public institutions or a constant care and expense to their families. It is estimated that syphilis is the primary cause of 15 per cent. of the first admissions to our civil state hospitals. In a recent article, Dr. Pollock[1] states that a census of patients in the civil state hospitals of New York at the close of the fiscal year, June 30, 1917, disclosed that 1,370 cases of general paresis and 122 cases of cerebral syphilis were under treatment. Estimating the cost of maintenance of patients of this type to the state and the loss of earnings resulting from their incapacitation the appalling figure of $5,398,644.99 was obtained. How can these tragedies to the individual and the expense and economic loss to the state be prevented?

They can be limited (1) by educating the public as to the far-reaching results of the disease and encouraging sexual continence, and (2) by instructing the individual how best to escape infection after exposure. After infection the future health of the patient is largely dependent on the knowledge of the physician under whose care he may have the good or bad fortune to entrust himself. If the physician has the proper conception of the problem and recognizes the great importance of carefully formulated and efficient treatment he may, after a definite time, be cured clinically and serologically and be assured that his future is secure. Failure on the part of his medical adviser to properly employ modern therapeutic methods and to control the result by accurate serologic examinations results in a cure of symptoms only and not of the underlying infection. The existence at this time of such a large number of cases of neurosyphilis is largely due to the state of knowledge of the disease when individual infection took place, and to the belief at that time that practically all types of syphilis of the nervous system resulted from a late invasion with the virus. Treatment was more or less perfunctory; the serology of the fluid was undeveloped and only the terminal stage of nervous system syphilis was vaguely understood. It is not surprising, therefore, that many individuals infected previous to the modern era of accurate diagnosis and more efficient treatment are now the victims of what we may conservatively regard as preventable sequelae of the disease.

---

* Read before the Section on Dermatology at the Sixty-Ninth Annual Session of the American Medical Association, Chicago, June, 1918.

* Because of lack of space, this article is abbreviated in The Journal. The complete article appears in the Transactions of the Section and in the author's reprints.

[1] Pollock, H. M.: The Economic Loss to the State of New York on Account of Syphilitic Mental Diseases During the Fiscal Year Ending June 30, 1917, Ment. Hyg., 1918, 2, 2.

We now possess accurate laboratory methods for the diagnosis of syphilis in practically all of its clinical forms together with specific drugs which, given in the proper manner and at the right time, are curative in the majority of cases. We also by a study of the pathologic changes in the various organs appreciate the great value of prophylactic treatment rather than an attempt to cure organs damaged beyond repair. The pathologist is always a therapeutic pessimist because he sees the end-results only of an infection. It should be our aim to teach methods which prevent such consequences.

INSTITUTIONAL INSTRUCTION

How can the knowledge at our command be utilized for the best interest of the individual and the community? In the first place, by a system of education by medical institutions with sufficient intelligence to grasp the importance of the problem. Institutions not organized for the benefit of a small group of favored men, but those which will give to the department of syphilology the same recognition they grant the departments of medicine and surgery. A teaching department organized on broad lines in our leading medical schools should serve as a center for the dissemination of accurate knowledge of this important infection. At present a vast amount of misinformation is conveyed to students by various departments in most of our teaching institutions. Theories and impressions not based on facts are seriously taught by men without a thought as to the results they will have on the future activity of the student of medicine. A professor of pathology in one of our universities belittles the value of the Wassermann reaction of which he knows nothing. Other medical men attach no value to the serology of the cerebrospinal fluid because they have not had an opportunity to correlate their clinical observations with long continued and accurate investigations along these lines. At this time more than any other in the past the problem is of the gravest importance to the state, as with the return of many infected soldiers foci of disease will be established throughout the country that will give rise to its wide diffusion. Dispensaries and hospitals should be properly equipped to diagnose and treat early as well as late forms of the infection and be controlled by men educated in modern methods of diagnosis and treatment who realize the difference between a clinical and a serologic cure. Many hospitals now refuse early cases of the infection when a cure is possible, but gladly receive interesting cases of incurable aneurysms, neurosyphilis and visceral syphilis. It is difficult to eradicate medieval ideas as to the great danger of infection from the minds of hospital authorities and to cause them to realize the value of prophylaxis. We fortunately possess in the city and state of New York departments of health which recognize the economic importance of syphilis and which provide ample laboratory facilities for its diagnosis. They are also active in educational campaigns and eventually will have a much deeper influence in safeguarding the public health from venereal infection than they have in caring for tuberculosis.

DEFINITION OF NEUROSYPHILIS

Neurosyphilis is employed as a comprehensive term to include all types of the disease which may involve one or all of the tissues of the central nervous system. The pathologic process may be limited to the blood vessels alone and give rise to a complex of symptoms due to partial or complete loss of blood supply to a definite area with resulting loss of function and eventual destruction due to softening. In this group we may have a clinical picture like that caused by cerebral arteriosclerosis of nonsyphilitic origin with vague symptoms, as headache, insomnia, loss of memory, inability to concentrate and mental depression. With gradual obliteration of the lumen of vessels supplying important centers or tracts, hemiplegias, paraplegias, monoplegias, aphasia, hemianopsia, convulsions, limited or generalized, may take place. As a result of localized or generalized arteritis, aneurysms and hemorrhages occur with pressure symptoms and tract degenerations accompanied, at times, by profound coma and death.

In uncomplicated vascular syphilis the cerebrospinal fluid may be entirely negative or show a marked globulin reaction, no excess of lymphocytes and either a positive or negative Wassermann reaction. The blood Wassermann may also be positive or negative. If the latter, a positive reaction may at times be activated by treatment. The results of serologic examinations in vascular syphilis are therefore frequently misleading. Damaged vessels often persist after the Wassermann reaction becomes negative and are the cause of cerebral or other hemorrhages or lesions due to thrombosis or partial vessel occlusion. Cerebral arteritis may be a part of a generalized arteriosclerosis with high blood pressure, cerebral hemorrhage and death, a condition not to be distinguished from the nonsyphilitic type in symptoms or terminal stage. Cerebral symptoms are often interpreted after the diagnosis of aortitis and blood pressure determination.

TYPES OF LESIONS

In early syphilis the lesions in the central nervous system are comparable to those met with on the cutaneous surface. They may be superficial and involve only the meninges or may extend to the brain substance itself. Early convexity meningitis is manifested by headache, vomiting, delirium and convulsions which lead to coma and at times to death. Localizing symptoms may be present or absent.

Case 3.—A man, aged 45, consulted me, April 26, 1916, with a primary lesion. His Wassermann reaction was ++++. He received seven intravenous injections of arsphenamin and sixteen injections of mercury, which treatment was followed by a negative test. He then left town. Early in October he suffered from general malaise, loss of appetite with nausea and vomiting in the early morning. A few days later he developed mild transient generalized headaches; and October 27, numbness of the right upper extremity followed by transient motor and sensory aphasia occurred. When seen October 30, he had a right-sided facial paralysis; all the deep reflexes were hyperactive and greater on the right side; the pupils were slightly irregular, reacting well to light and accommodation but did not hold when contracted. His blood was ++++ and a spinal puncture revealed: cells, 944; globulin, ++++; Wassermann reaction, ++++ to 0.2; colloidal gold test, 5555542100. Six intravenous and eleven intraspinal injections with eighteen injections of mercury restored the patient to his former good health. His headaches and numbness disappeared after the second intraspinal injection, and he had no more attacks of aphasia. His fluid and blood have been negative since May, 1917.

Case 4.—A physician developed an initial lesion on the thumb in November, 1916, followed by secondaries. He received immediate treatment with arsphenamin and mercury. Two months later he had right-sided parietal headaches. A lumbar puncture made in May, 1917, was said to show 104 cells, the other findings being weakly positive. He received three intraspinal injections, after which the fluid was reported negative. His headaches did not entirely disappear and became more intense a few months later. He suffered from insomnia, great depression, impaired mental processes and lost 24 pounds in weight. I saw him Nov. 20, 1917. A few days later, while in the sanitarium, he became excitable and wildly delirious, his delirium lasting several days. Spinal puncture revealed: cells, 416; globulin, +++; Wassermann reaction, ++++ to 0.4; colloidal gold test, syphilitic curve. The serum was negative. Treatment: Seven intravenous and six intraspinal injections, with a course of mercury, were given. All the clinical symptoms vanished and the fluid rapidly became negative.

These cases are usually more acute and rapid in development than the late types of meningitis. Pupillary changes are, as a rule, absent or only slight. In basilar meningitis localizing symptoms are more often met with because of the anatomic structure of the base. Cranial nerve paralyses and pupillary changes usually indicate the onset of this type which frequently shows no subjective symptoms and is only indicated by objective signs as pupillary irregularity and changes in the light reflex. Third nerve palsy is most frequent: occasionally the facial and auditory nerves are involved as well as the optic.

SEROLOGY

The examination of the spinal fluid gives an accurate index of the intensity of the process and usually shows most positive phases in the convexity type in which the pleocytosis may reach a count of 800 or 900, or even 2,000 or 3,000 with positive globulin and a positive Wassermann reaction in the higher dilutions together with a paretic gold curve. In basilar meningitis we may also find marked serologic changes, but sometimes only one or more phases positive in the early development of the process. A sharp limitation of the infection to one nerve or its nucleus may cause pupillary changes or oculomotor paralysis with little or no change in the fluid. These cases may terminate in a spontaneous cure with local damage and no tendency to progress.

EARLY APPEARANCE OF SYMPTOMS

Disseminated forms of cerebrospinal syphilis are met with in the first months of the infection with symptoms referable to the cord meninges as well as to the brain coverings. A careful interrogation of patients with advanced neurosyphilis will often elicit the information that paresthesias, bladder weakness, girdle sensations or rectal disturbances were noted in the early months of their infection. These symptoms at times regressed under treatment, but usually recurred with greater intensity at a later period. Such symptoms without doubt indicate early cord involvement and, when untreated, terminate in typical tabes or spinal syphilis.

A proper comprehension of the late forms of neurosyphilis is possible to one who can visualize the manner in which the tissues react to the infectious agent which invades the cerebrospinal fluid early in the disease. Foci are established in the blood vessels of the brain or cord meninges or the parenchymatous structure of the nervous system, which may remain latent for years or slowly compromise by pressure or degeneration important centers or tracts with resulting focal or general symptoms. As in the skin, a syphilitic process may spontaneously subside in one place and reappear in another. It may rapidly cause a local destructive lesion with definite focal symptoms, a slow invasion of an important center, or a gradual degeneration of cord tracts or the cerebral parenchyma. It is not surprising, therefore, that the symptomatology is so varied and simulates so frequently lesions due to other infections or new growths. An invasion of the brain parenchyma may be present for years with few or no symptoms, if the meninges or important centers are not implicated. The character of the lesions may only be revealed by the serology of the fluid.

INTERPRETATION OF SPINAL FLUID FINDINGS

Observation of a large number of cases during the past six years, in which the clinical manifestations have been carefully correlated with the serologic findings, convince me that the symptomatology should be largely restudied and interpreted from a serologic as well as from a clinical standpoint. Fluid findings enable us to differentiate more accurately the symptoms due to pure vascular syphilis, meningovascular or parenchymatous. It enables us to prognosticate the outcome of certain types and to understand why the deeper forms resist all treatment and eventually terminate in incurable conditions. The latter type may have few symptoms but show a serology which offers the gravest prognosis, the former, acute and menacing symptoms which readily yield to treatment and terminate in complete recovery. The statements so often made that no information is afforded by spinal examinations is, in my experience, entirely erroneous and misleading.

A low grade parenchymatous encephalitis with slight or no meningeal involvement may exist for years with indefinite symptoms often wrongly interpreted. A slight character defect, loss of ambition, forgetfulness, irascibility, mental depression, so-called neurasthenia, symptoms terminating in a nervous breakdown, often precede for years the final stages of paresis and go unrecognized until an accidental eye examination reveals pupillary changes. Patients have come under my care in whom the diagnosis was only made after a sudden loss of consciousness following some unusual mental effort or without assignable cause. Spinal fluid examination reveals the real condition and enables one to correctly predict the patient's future.

SYMPTOMATOLOGY

In cord syphilis and tabes the early symptomatology may be equally vague and long unrecognized. Gastric crises are taken for appendicitis, gastric ulcer, floating kidney, gallbladder involvement, and patients having such symptoms often go to the operating table. Rectal and bladder crises are attributed to local conditions. Leg pains are called sciatica or rheumatism and may precede for years definite disturbance in gait. A radiculitis may exist with pains for months or years before definite involvemnt of the tracts takes place. The serology in such cases is definite and affords diagnostic and prognostic indications of the greatest value.

The symptoms which cause the patient to consult a physician aside from such evident ones as double vision, marked headache, convulsions, severe tabetic pains or paralyses are the following: vague fears resulting from a knowledge of old infection, weakness of the bladder and impaired sexual power, loss of memory, impaired business judgment, speech disturbance, gradually increasing motor aphasia, complaint on the part of the family or business associates as to increasing irritability or unreliability of the patient, changes in personality, and character defects foreign to the normal state.

In a paper of this character a complete syndrome cannot be given. It is only suggestive and intended to point to the necessity of correlating clinical and laboratory study. It must always be kept in mind that, while the syphilitic inflammation may limit itself sharply to one or the other of the tissues mentioned, pure types are the exception rather than the rule, and that complicated and transitional forms are usual and confuse the clinical diagnosis. A hemiplegia due to an arteritis and hemorrhage may give a high cell count (in one case 1,100) indicating an accompanying meningitis. A gummatous meningitis involving the convexity follows the pial vessels into the brain cortex and may give the clinical picture of a paresis or brain tumor. Treatment in such cases may result in a more favorable outcome than indicated by the serology. Psychoses without the earmarks of paresis with positive fluid findings point to a cerebral encephalitis of unusual localization.

Neurosyphilis may also be complicated with chronic alcoholism as well as with a nonspecific arteriosclerosis. t may be activated after a long period of latency by rauma, unusual mental strain, and by the stress and traumatisms of war. In the routine examination of the officers' training camps several patients have come under my care in whom the condition was revealed by a systematic neurologic examination without previous knowledge on the part of the patient. Under active war conditions an acute activation of the trouble would doubtless be brought about. Railway spine is likewise a not infrequent activation of a latent syphilis in this region.

In a former communication,[2] I referred to the existence of conjugal and family groups of neurosyphilis and quoted some of the available statistics. I also referred to Nichol's experimental work and strain of *Spirochaetae pallidae* recovered from the spinal fluid. The work begun by Nichols has subsequently been carried on by Reasoner, Wile, Zinsser and Hopkins, and others. Reasoner's[3] results were presented in a paper in 1916. He was able to demonstrate fixed differences in various strains of spirochetes as studied in the rabbit. Organisms recovered from the nervous system of patients with early cerebrospinal syphilis produced in the rabbit's testicle a definite type of orchitis with tendency to central necrosis and with eye changes, choroiditis and chorioretinitis in 75 per cent. of the inoculations. Eye involvement in the rabbit is, in his opinion, suggestive of a high degree of invasiveness or predilection for the human nervous system. The knowledge we have acquired regarding types of pneumococci and strains of streptococci and other organisms strongly suggest that the spirochetes may acquire certain changes in biologic characters by repeated passage through the central nervous system of the host. Racial immunity to neurosyphilis of which we have some clinical evidence strengthens the theory of strains of the syphilis organism with highly invasive power.

The following series illustrates the incidence of neurosyphilis in closely related individuals:

REPORT OF CASES

Group 1.—C. (husband), aged 55, had tabes, but gave no history of infection. There were typical neurologic signs of locomotor ataxia. Spinal puncture revealed: cells, 54; globulin, +; Wassermann reaction, ++++ to 0.4; colloidal gold test, 2233210000. Serum, ++.

C. (wife), aged 52, had tabes, but gave no history of syphilis. Married 30 years; no children; seven or eight miscarriages. Pronounced symptoms of tabes. Spinal fluid revealed: cells, 5; globulin, ++; Wassermann reaction ++++ to 0.6. Serum, ++++.

Group 2.—M. (husband), aged 63, had taboparesis, but gave no history of infection. Tabetic symptoms were present for years. Mental disturbance and right hemiplegia occurred in 1912. Spinal fluid: strongly positive. Serum, ++++.

M. (wife), aged 62, had taboparesis. In 1897, the ovaries and uterus were removed for gonorrheal salpingitis. In 1907, she developed insomnia and difficulty in walking. In 1910, melancholia and suicidal tendencies appeared. Spinal fluid was not obtained for examination.

Group 3.—C. (husband), aged 35, has tabes. The chancre and secondaries appeared at age of 17. There was no subjective complaint. Objectively, the patient has Argyll Robertson pupils and loss of deep reflexes. Spinal puncture revealed: cells, 4; globulin, ++++; Wassermann reaction, + + + + to 1 c.c. + 0.8. Serum, + + + +.

C. (wife), aged 32, has tabes with optic atrophy. She has been married fifteen years; four miscarriages; one healthy child. No cutaneous symptoms. Six months after marriage she had a right-sided facial palsy. Twelve years later pronounced tabes occurred with rapid loss of vision of the left eye and impairment of the right. Spinal puncture revealed: cells, 67; globulin, ±; Wasserman reaction, ++++ to 0.4. Serum, ++++.

Group 4.—D. (wife), aged 62, had paresis, but gave no history of infection. For many years she has been nervous. In 1913, she had attacks of syncope with nausea and vomiting; in 1916, coma lasting three or four days occurred. Changed pupillary and deep reflexes, tremors, speech disturbances and memory defects were present. Spinal puncture revealed: cells, 7; globulin, ++++; Wassermann reaction, ++++ to 0.2; colloidal gold test, 5544433000000. Serum, ++++.

D. (husband) died of paresis.

Group 5.—N. (wife), aged 33, had cerebrospinal syphilis, but gave no history of infection. Married ten years; no miscarriages. One child, 5 years old, has congenital syphilis.

For nearly a year she had been very nervous and irritable; complained of extreme exhaustion; occipital headaches and pains in extremities. Pupils were irregular, unequal and sluggish to light. The deep reflexes were hyperactive and unequal. Spinal puncture revealed: cells, 80; globulin, ++++; Wassermann reaction, ++++ with 2 c.c.; colloidal gold test, 5555410000. Serum, +.

N. (husband) died of paresis.

N. (son), aged 5 years, is mentally retarded, but has no physical defects excepting external strabismus of left eye. Spinal puncture revealed: cells, 1; globulin, ±; Wassermann reaction, — with 2 c.c.; colloidal gold test, 1111000000. Serum, ++++.

Group 6.—N. (husband), aged 50, had paresis, but gave no history of syphilis. In 1914, he developed typical paretic speech, mental defects and somatic signs. Spinal puncture revealed: cells, 16; globulin, ++; Wassermann reaction, ++++ to 0.2; colloidal gold test, 5555543100. Serum, ++++.

N. (wife), aged 33, had cerebrospinal syphilis. Married nine years; one miscarriage; two children died in infancy. One living child 5½ years old has congenital syphilis. She complained of headaches, insomnia and nervousness, and had pupillary changes and unequal reflexes. Spinal fluid not obtained. Serum, +.

N. (son), aged 5½ years, was mentally defective. Spinal fluid and serum were negative, but these examinations were made after the child had received prolonged treatment.

Group 7.—G. (father), aged 43, had cerebrospinal syphilis. The chancre appeared in 1901, and in 1909 there was paresis

3. Reasoner, M. A.: Some Phases of Experimental Syphilis, The Journal A. M. A., Dec. 16, 1916, p. 1799.

of left leg and bladder paralysis. Spinal fluid was not obtained. Serum, —.

G. (daughter), aged 12, is feeble-minded. She has hutchinsonian teeth and arched palate. Is negative neurologically. Spinal fluid was not obtained. Serum, ++++.

Group 8.—E. (mother), aged 31, had tabes. She has been married eleven years; no cutaneous symptoms. Neurologically, she presents Argyll Robertson pupils and absent deep reflexes. Spinal puncture revealed: cells, 18; globulin, ++++; Wassermann reaction, ++++ to 0.4; colloidal gold test, 1223321000. Serum, ++.

E. (son), aged 8½, has cerebrospinal syphilis with unequal, irregular and fixed pupils. He is very nervous and was removed from school because of lack of cooperation, inability to grasp instruction and violent temper. Spinal puncture revealed: cells, 2; globulin, ++; Wassermann reaction, ++++ to 0.2; colloidal gold test, 5555543100. Serum ++++.

Group 9.—K. (father), aged 38, had paresis. The chancre appeared in 1904, and delusions of grandeur in 1911. Death from paresis in 1916. Spinal puncture revealed: cells, 86; globulin, ++; Wassermann reaction, ++++ to 0.2. Serum, ++++.

K. (child), aged 5, had hydrocephalus when an infant. When 5 years old interstitial keratitis developed.

Group 10.—E. (husband), aged 44, had cerebrospinal syphilis (paraplegia).

E. (wife), aged 35, had hemiplegia and evidence of disseminate cerebrospinal syphilis.

Group 11.—S. (husband), aged 36, had paresis, the chancre appearing in 1905. In 1907, delusions of grandeur developed and he was committed to one of the state hospitals. Spinal puncture revealed: cells, 127; globulin, ++; Wassermann reaction, ++++ to 0.2; colloidal gold test, paretic curve.

S. (wife), aged 35, had incipient paresis, the chancre and secondaries appearing in 1909. In February, 1918, she developed paralysis of the third and fourth nerves. Argyll Robertson pupils, extreme nervousness and insomnia were present. Spinal puncture revealed: cells, 9; globulin, ±; Wassermann reaction, ++++ to 0.6; colloidal gold test, 5555543100. Serum, ++++.

Group 12.—M. (wife), aged 31, has tabes, but she denied syphilitic infection. Married seven years; no children; one induced miscarriage. She has subjective and objective manifestations of tabes. Spinal puncture revealed: cells, 2; globulin, —; Wassermann reaction, ++++ to 0.4; colloidal gold test, syphilitic curve. Serum, +++.

M. (husband) is in a state hospital with paresis.

Group 13.—K. (husband), aged 44, had optic atrophy. The chancre appeared in 1914 with secondaries of skin and mucous membranes. In 1916, his vision became impaired. Spinal puncture revealed: cells, 10; globulin, +; Wassermann, reaction, ++++ with 2 c.c.; colloidal gold test, 5555542000. Serum, ++++.

K. (wife), aged 25, had incipient paresis (?); a late secondary eruption appeared in September, 1915. She presents unequal pupils, hyperactive reflexes, more so on right side. Spinal puncture revealed: cells, 185; globulin, +; Wassermann reaction, ++++ to 0.2; colloidal gold test, paretic curve. Serum, ++++.

Group 14.—R. (husband), aged 35, had incipient paresis, but gave no history of infection. In April, 1918, left-sided hemiplegia developed. Spinal puncture revealed: cells, 7; globulin, +; Wassermann reaction, ++++ to 0.2; colloidal gold test, paretic curve. Serum, ++++.

R. (wife), aged 30, has cerebrospinal syphilis. The pupils are unequal and irregular with sluggish light reaction; unequal exaggerated deep reflexes; headache and insomnia. Specimen of spinal fluid not obtained. Serum, ++++.

Group 15.—W. (father), aged 35, had cerebrospinal syphilis. Date of infection unknown. Unequal, irregular pupils; hyperactive reflexes, more so on right side. Spinal puncture revealed: cells, 25; globulin, +; Wassermann reaction, ++++ with 2 c.c.; colloidal gold test, syphilitic curve. Serum, ++++.

W. (mother), aged 32, had cerebrospinal syphilis. No signs of syphilis developed until syphilitic child was born five years ago and strongly positive Wassermann reaction was discovered. Argyll Robertson pupils were present and the deep reflexes were exaggerated, more so on right side. Spinal puncture revealed: cells, 2; globulin, ±; Wassermann reaction, ++++ to 1.5; colloidal gold test, syphilitic curve. Serum, ++++.

W. (daughter), aged 5, had juvenile paresis. When 3 months old she had a syphilitic eruption; at age of 18 months a hemiplegia developed; at age of 4 years epileptiform attacks occurred. Spinal puncture revealed: cells, 140; globulin, ++++; Wassermann reaction, ++++ to 0.2; colloidal gold test, paretic curve. Serum, ++++.

W. (son), aged 2½ years, has cerebrospinal syphilis. He has always been a healthy child; is bright and appears normal. Has unequal pupils. Other findings negative. Spinal puncture revealed: cells, 12; globulin, —; Wassermann reaction, ++++ with 2 c.c.; colloidal gold test, syphilitic curve. Serum, ++++.

Group 16.—P. (father), aged 46, had optic atrophy. The chancre and secondaries appeared in 1898. The patient was well until 1916, when his vision became impaired. Fluid examination was not obtained. Serum, ++++.

P. (wife), aged 42, had tabes, but gave no history of an initial lesion or secondaries. Married in 1899. For seven years she has suffered with gastric crises; has classic signs of tabes. Spinal puncture revealed: cells, 37; globulin, none; Wassermann reaction, ++++ to 0.6; colloidal gold test, 1123100000. Serum, ++.

P. (child), aged 11, was considered a normal child until school authorities reported that she was backward. Has grown very nervous and has increasing difficulty in learning. Has Argyll Robertson pupils. Spinal puncture revealed: cells, 1; globulin, +; Wassermann reaction, ++++ with 1 c.c.; colloidal gold test, syphilitic curve. Serum, ++++.

Group 17.—S. (son), aged 20, has juvenile paresis with optic atrophy. He is underdeveloped, completely blind and helpless. Spinal puncture revealed: cells, 15; globulin, +++; Wassermann reaction, ++++ to 0.2; colloidal gold test, paretic curve. Serum, ++++.

S. (father) died of paresis.

S. (mother), aged 38, gives no history of initial lesion or rash. Physical examination is negative; her blood has been repeatedly negative, and a lumbar puncture made recently was also negative.

Group 18.—P. (wife), aged 25, has incipient paresis and denied syphilitic infection. Argyll Robertson pupils. Unequal reflexes and beginning deterioration. Spinal puncture revealed: cells, 50, globulin, ++++; Wassermann reaction, ++++ to 0.2; colloidal gold test, paretic curve. Serum, ++++.

P. (husband) is now in a state hospital with paresis.

Group 19.—H. (husband), aged 38, has clinical symptoms of tabes. Permission for spinal puncture has not been granted. Wassermann reaction was ++++.

H. (wife), aged 34, has all the neurologic signs of tabes. Has not permitted a spinal puncture. Serum, ++++. She has a son, aged 10, who gives positive blood reaction and has a perforated palate, but no neurologic signs.

NEUROSYPHILIS IN THE ARMY

The thorough and scientific organization of the Army and Navy medical staffs in charge of venereal diseases with the cooperation of the medical section of the Council of National Defense has been followed by a marked decrease in the incidence of the venereal menace among the enlisted personnel. The scientific study of syphilis before the outbreak of war by Nichols, Reasoner, Craig, Vedder and others was largely influential in disseminating modern methods of diagnosis and treatment among the medical officers of the Army. This work has been ably supported since our entry into the war by the committee appointed by the Surgeon-General of the Army under the immediate direction of Colonel Russell. Many of the reserve medical officers have had intensive training in the army medical schools and in venereal clinics, and now in active service are gradually acquiring exact technical skill. I have received a number of communications from former assistants and pupils which show a keen grasp of the syphilis problem and a constant endeavor to enlarge their knowledge.

The importance of early recognition of neurosyphilis and its significance to the future activity of the individual might here be emphasized. Medical officers should be instructed in the present day methods of spinal fluid examinations and learn to interpret the significance of the various positive phases which may be present. The treatment of neurosyphilis aside from the use of arsphenamin intravenously and mercury intramuscularly is perhaps too technical for general employment in the Army. Patients who show such involvement and who do not yield to the methods easy of application should be sent to a base hospital or discharged from the service and referred to a clinic equipped to treat them.

Examination of recruits and officers in the training camps has revealed the presence of neurosyphilis in individuals who either were unaware of their infection or who had considered themselves cured and were suffering no inconvenience from the nervous system involvement. Within the past year, I have seen a number of men who have been rejected because of pupillary anomalies; many of these patients have such slight signs that they are only demonstrated by the rigorous examinations now demanded on the part of the Army.

IMPORTANCE OF LABORATORY TESTS

The value of spinal fluid examination as a diagnostic measure in neurosyphilis is becoming more generally recognized among syphilographers and neurologists. Standardized methods are, however, not as frequently employed as they should be. Many laboratories report only a positive Wassermann reaction without titration of the fluid in strengths of from 2 to 0.2 c.c. or less. Others employ only 0.5 c.c. of fluid and thus fail to obtain a positive reaction in fluids which would give it in larger quantities. The reaction in many cases of tabes and cerebrospinal syphilis has been reported as negative because of failure to use the larger amounts of fluid. On the other hand, the presence of a strongly positive Wassermann reaction in the higher dilutions indicates a more serious type of infection and taken with a paretic gold chlorid reaction suggests paresis or preparesis. We can, therefore, prognosticate with a fair degree of accuracy the eventual outcome of our cases of neurosyphilis by properly performing and interpreting our fluid serology and observing the effects of treatment.

TREATMENT

Treatment begun in primary and very early cases of secondary syphilis doubtless prevents infection of the spinal fluid, but it is impossible to say how much value treatment has in preventing the invasion of fully developed secondary syphilis, for at that time involvement may already have taken place. A recognition of this possibility with properly applied diagnostic and therapeutic methods readily controls early syphilitic meningitis as illustrated in the cases previously quoted and will prevent the degenerative sequelae which follow the long years of latency.

In order to emphasize again the importance of early lumbar puncture and careful and repeated neurologic examinations, I would like to cite another case:

A man who presented himself with a secondary rash in February, 1917, received fifteen injections of arsphenamin and thirty of mercuric salicylate. While under treatment in July, he complained of severe headaches; these occurred in October with marked vertigo and ataxia. At that time, examination revealed pupillary inequality, hyperactive reflexes and a very strongly positive spinal fluid. In another instance, a patient who was in the second year of the infection came complaining of pains about his knees. He had had thirty-two injections of arsphenamin, over 100 injections of mercury and many inunctions. The only neurologic abnormality was beginning Argyll Robertson pupils. The spinal fluid revealed: cells, 24; globulin, ++; Wassermann reaction, ++++ to 0.2; gold chlorid test, 1233100000.

CONCLUSIONS

In the past decade much progress has been made in our knowledge of the nature, development, prognosis and treatment of neurosyphilis. The various types had been correlated with the serology of the blood and spinal fluid and a fairly firm foundation established on which to build in the future. By carefully conserving the data now available, we may be able later to answer some of the questions which so deeply involve the patient's future health and the community's welfare. Some of these questions are the following:

1. Are the present criteria of cure all that are demanded to insure against a relapse of the infection?
2. Assuming that we have a negative blood Wassermann during a year after treatment is discontinued which remains negative after a provocative arsphenamin injection and that the spinal fluid is not infected, the following questions come up for consideration:

(*a*) Can we assure the patient with certainty against a recurrence? A mathematical reply cannot be made to these queries, but up to this time we have seen no relapses in patients who have complied with the criteria in question. All the evidence favors the view that a serologic and clinical cure will remain permanent. It is always possible, however, for spirochetes to be hidden away in some of the tissues too few in number to produce the Wassermann reaction but which may be activated at some future time and produce tissue reactions. This possibility has been observed in syphilis of the eye and in arteritis of undoubted syphilitic origin.

(*b*) Does freedom of the nervous system from infection in the first year with a positive blood Wassermann indicate that such infection cannot occur later from an uncured focus? This question can only be answered when we carefully compare the data obtained from cases of early infection with future observations of such patients. All institutions and physicians should therefore preserve carefully all records, serologic and clinical, and compare them with those obtained in future examinations. Standardized methods of diagnosis and treatment (amount and kind) with results should be adopted and preserved in the form of a medical register like the one used in the medical department of the Army.

A Patriotic Duty.—To be free from disease, or, if, unfortunately for ourselves, we cannot be free from disease, to prevent by every precaution, the spread of our disease to others, is one great thing we can do for our country.—Editorial, *Minnesota Public Health Association Journal.*

SYPHILIS AND VENEREAL DISEASES AS A PUBLIC HEALTH PROBLEM *

H. G. IRVINE, M.D.

Director of the Division of Venereal Diseases, Minnesota State Board of Health; Assistant Professor of Dermatology and Syphilis, University of Minnesota Medical School; Director, Bureau of Venereal Diseases, California State Board of Health, October, 1917, to April, 1918

MINNEAPOLIS

Health authorities ought to be concerned with all diseases which, being infectious and communicable, are likely, through their spread, to endanger public health. It is said that the knowledge necessary to control such a disease consists of the recognition of the causative germ, its method of being carried and the having of a specific therapy. For years we have known the germs of syphilis and gonorrhea, have been perfectly cognizant of how both diseases are carried, and have had at hand a more or less specific therapy. More than that, we have known that continence is entirely consistent with health, and that it is an almost sure preventive of both diseases; and yet, we have hesitated as individuals and as a profession to go on record for it. We have even hesitated, and perhaps with good reason, to advocate those well known artificial means of prevention which the Army and Navy have demonstrated to be so valuable.

The public at large has been inclined to discount what seemed to it unbelievable figures of the prevalence, and the havoc wrought by venereal disease, and has not shown a willingness to be informed, in plain language, of all the facts. This has led to the nefarious practice of making these diseases "secret diseases," in fact as well as in name, and with a full knowledge that a goodly proportion of innocent persons were constantly being infected, we still have tolerated this policy of silence. It has taken a war to wake us up and make it possible to attempt to handle these diseases along the same lines that other infectious and communicable diseases are handled. The government knows full well that we must have well soldiers if we would win this war; it also knows that with every war there has been a marked increase in venereal diseases, and that the control of these diseases among the enlisted men would be its greatest disease problem. These facts were given full recognition when, early in the war, a very definite and complete program was adopted for the early diagnosis, treatment and control of venereal diseases. Not, however, until the mobilization of our draft Army did any one fully realize the very great need of the rapid extension of a similar program to the civil population. When it was seen from the figures produced that the venereal disease rate of civilians was several times greater than had been the rate in the Regular Army, the War Department, particularly through the Surgeon-General's Office began to call on the public health officials of various states to undertake definite campaigns to control these diseases. The fact that nearly every family in the land has had or will have a very personal interest in our Army makes the public sympathetic to this work as it has never been before.

California was, I think, the first state to answer the call, and made an appropriation, from war emergency funds, of $60,000 for the organization of a bureau of venereal diseases in the state board of health. Minnesota followed a few months later with an appropriation of $35,000 for the creation of a similar division. In both cases the funds are to run to the next meeting of the legislatures; for California this means two years; for Minnesota, one year.

In all of the work, one fundamental fact has been kept in view, namely, the absolute need of recognizing the complexity of the problem and of coordinating the work of all groups interested in any particular angle of the attack. Generally speaking, this is in contrast to any previous method under which all of us have seen failures registered because of the necessary limitations.

PROGRAM OF ATTACK

The program for a state divides itself logically into four parts. These will be considered in the order of their importance from the standpoint of their effect on the reduction of disease. The first three parts are concerned with the control of three distinct groups of patients, the fourth part with educational work.

THE CARRIER

The first group of patients with which we are concerned is the one in which enforced quarantine and treatment are necessary. Here are included the great carriers of these diseases, the prostitute, both professional and clandestine, prisoners and inmates of institutions, and incorrigible patients. So far as prostitution is concerned, there must be active cooperation of the police departments and courts in suppressing as far as possible all prostitution. This action will make prostitutes inaccessible, and so reduce exposures; reduction of exposures is bound to reduce infections. Examinations should be made in all cases and quarantine instituted in a hospital or other suitable place.

EFFECT OF LAW ENFORCEMENT ON EXPOSURES AND INFECTIONS

Month	Mean Strength of Command	Venereal Diseases, New Cases	Exposures Represented by Prophylactic Treatments
October	13,813	193	951
November	16,138	101	669
December	17,532	124	623
January	18,068	61	378
February	17,315	86	478

The effect of this work is very nicely demonstrated by some figures collected in San Francisco.[1] In the first place, the problem was rapidly reduced, as shown by the fact that in October before the work started, nearly 400 women were brought into court on charges of moral turpitude. Soliciting on the streets was rampant. November 1, arrangements were made for jail sentences in all cases with quarantine and treatment of those found diseased. During November only about 150 appeared in court, and the streets were clean. The number continued to decrease, until in February less than 100 were arrested.

The effect on exposures and infections is shown by the accompanying table in which it is seen that in the first month exposures, which may be represented by prophylactic treatments, were reduced nearly 300, while infections were practically cut in two, and this in spite of the fact that the strength of command shows an increase of nearly 3,000. As time went on, many other elements undoubtedly entered into the reduction; but there was apparently no other explanation

---

[1] Statistics compiled by Lieut. Allison T. French, Sanitary Corps, U. S. N. A.

for this rapid reduction taking place immediately following law enforcement. Another point to be emphasized in the table is that in February the same judge was on the bench as in October, and he was the one of the four who rotated in this court who was most reluctant in agreeing to the government's demands. Consequently, we see during his month an increase in exposures and a corresponding increase in infections. This table apparently demonstrates that, to a certain extent, exposures and infections follow the enforcement or nonenforcement of law.

While this law enforcement will have a deterrent effect on a certain number of prostitutes, it should not be understood that the work ends with this or their medical treatment; if it did, it would be wasted since on release they would immediately return to their profession and become reinfected. It will be necessary that adequate provision be made for the permanent custodial care of the feebleminded, and for those confirmed offenders who can be forced into a life of decency only by long term commitments to reformatories. By bringing proper social service agencies in contact with the younger offenders, they may almost immediately be returned to society.

The professional prostitute is a prolific spreader of disease, as she nearly always has gonorrhea, which may be chronic in nature, and particularly because, if allowed to practice her profession openly, she daily exposes from ten to twenty or more patrons. From the standpoint of syphilis she is not so important, as she contracts it early in her career and thereafter is likely to take sufficient treatment to keep the disease under control. Clandestine prostitutes are a danger, not so much on account of the number of persons they expose individually, but because there are a great many more of them, and being youthful offenders, they are more likely to be acutely infected and less well informed as to the care of themselves and their patrons.

In the examination of several hundred prostitutes in San Francisco, Sperry[2] found only two or three with demonstrable lesions of syphilis. In an examination of 731 women, Stevens[3] found 147 infected with gonorrhea, 243 with syphilis, and ninety-six with both syphilis and gonorrhea.

In carrying out this work in California, nearly $100,000 was appropriated by various communities of the state, and special isolation hospitals were built in San Diego and Los Angeles. The one in San Diego has thirty-five beds, and the one in Los Angeles, fifty-four beds. San Francisco arranged for a ward of thirty beds in the San Francisco Hospital, and a budget has recently been passed for approximately $50,000 for next year, which not only will permit the carrying on of this work in the hospital, but also will provide for a place of detention at the County Relief Home, which will care for from fifty to 100 inmates. Many of the smaller communities of the state have arranged for the detention of such patients in their county hospitals. Generally speaking, there is greater need for places of detention with proper hospital facilities than there is for straight hospital quarters, as many of these persons are properly ambulatory patients.

There should be an effort to make investigations of appropriate groups, and institute treatment when indicated. In most cases state prisons provide adequate hospital and medical facilities, but rarely do we find any attempt made to examine and treat prisoners in city and county jails. Here we have a class of people who are naturally prone to have no regard for the rights of others, and who are likely to have syphilis or gonorrhea. Arrangements should be made for a careful examination, including a Wassermann test of every prisoner, and proper treatment instituted. If necessary, cases should be quarantined beyond the time of sentence, so that in no case would an individual be allowed his freedom while still in an infectious condition.

During the months of February and March there were examined in the city and county jail in Los Angeles 681 male and female prisoners, 389 of whom were infected, and more than 7,000 treatments were given.

An examination was recently made of forty-three women and 145 men in the Minneapolis City Workhouse. Of the women, fourteen had gonorrhea, nineteen positive Wassermanns, and six had both syphilis and gonorrhea. Of the men, seven had gonorrhea, fifty had positive Wassermanns, and two had both syphilis and gonorrhea, thus making a total of seventy-seven diseased persons out of 188 examined. In general, when surveys have been made of the inmates of jails, approximately 20 per cent. have been found to have syphilis, and nearly 50 per cent. to have syphilis or gonorrhea. These figures indicate the great need that this work be undertaken with this class of people, who, we must realize, will not take the care of themselves necessary to prevent infecting others.

DISPENSARY PATIENTS

Investigations have shown that not more than from 30 to 50 per cent. of the patients infected with gonorrhea or syphilis receive adequate medical service at the hands of private practitioners. This has been due partly to the fact that many physicians are not sufficiently trained in the care of these diseases, and partly to the fact that a great many patients coming to them could not afford to pay for sufficient treatment to arrive at a cure. It is also a fact that a large number of patients, particularly of the poorer classes, go to drug stores, and, of course, it is obvious that treatment received in this way is worthless.

Investigations of certain dispensaries in the East have shown that approximately 50 per cent. of their men patients with gonorrhea attempt drug store treatment before they come to the dispensary.

If there is an insufficient number of specially trained physicians, and if the majority of the people cannot afford to pay the fees of specialists, it is perfectly obvious that there is a great need for more and better dispensary facilities, where people can obtain either free, or for a nominal sum, expert services. We should remember in this regard that we are not concerned entirely with the individual patient, but that to a certain extent we are providing for him in order properly to protect the community. The fact must also be emphasized that unless all of these cases are treated until cured, not very much is accomplished from the public health standpoint. This, of course, is more true of gonorrhea than of syphilis, since the one is infectious so long as present, whereas the other may be rendered temporarily noninfectious. But the great need is to place patients in such a condition that they will not be dangerous to others, and this means, generally speaking, a cure.

---

[2] Sperry, J. A.: Venereal Disease Control in San Francisco by the Board of Health, California State Jour. Med., 1918, **16**, 120.

[3] Stevens, W. E.: Gonorrhea in Women, California State Jour. Med., 1918, **16**, 260.

The man or woman who can afford to pay for only a little treatment should be sent at once to a dispensary or hospital where sufficient and expert treatment may be received.

Pressure should be brought to bear to see to it that every hospital supported by public funds admits all syphilis and gonorrhea patients on exactly the same basis as other patients are admitted, as there would seem to be no sense in their refusing on the one hand to admit active cases of gonorrhea or syphilis, while on the other hand, it is a fact that their wards are continually filled with the end-results of both of these diseases.

The problem of dispensaries is more acute in many of the smaller cities of 40,000 or 50,000 population than it is in the larger cities where there are already in operation either city or university clinics. It is being proposed, therefore, in many of the states, that a number of dispensaries be established in proper places throughout the state, either directly under the state board of health, or, at least, stimulated and officially recognized by it. In states in which there is a sufficient appropriation, a subsidy will be granted communities to assist in establishing these dispensaries, and it is quite possible that by making a nominal charge for treatment the dispensaries can be almost self-supporting.

In nearly all states in which the work is going on, provision is made for free arsphenamin, and these clinics can be made the official distributing points for this treatment. This plan is in accordance with the program that is being followed by Great Britain, namely, that of the federal government stimulating the organization of such clinics, and providing for 75 per cent. of the expenses, while the local communities take care of the other 25 per cent.

Unless the work of these and all other dispensaries is developed to conform to certain standards, the results will hardly be a success. But if certain standards are required such as the provision of a trained staff, sufficient rooms and equipment, nurses and social service workers, good results are almost bound to be attained. There are two distinct ways of insisting that these dispensaries be run according to standards laid down by the state board of health. In many states the board of health has the power to license dispensaries, and definitely control them, and in others, it will be possible by withholding official recognition, or by withholding the free arsphenamin, to see that the standards are followed.

It is very important that the states supply free laboratory service for the diagnosis of both gonorrhea and syphilis.

In California many local health departments were already operating dispensaries in connection with their work, and in many of these a department of venereal diseases was added. In San Diego such an outpatient department was instituted for both men and women. In Los Angeles an evening clinic for men was already in operation, and this has been enlarged, with very much better equipment, and now provides adequate service for both men and women. In May this clinic registered forty-six new cases, and had a total of 136 patients under treatment. San Francisco has depended in the past on the dispensaries of several medical schools. Their new budget, which has been granted, provides for a day and evening outpatient clinic for both men and women at the San Francisco Hospital. In Fresno the county hospital arranged for a ward for venereal diseases, and instituted an outpatient service, with a proper social service department, and within a month's time had thirty-five cases of syphilis under treatment. In Bakersfield a similar arrangement was made at the county hospital. In Santa Barbara a new contagious disease hospital is near completion, and arrangements have been made to have a portion of this devoted to venereal diseases. In Oakland and Sacramento the local health departments have both inaugurated clinics for venereal diseases.

In Minnesota arrangements are being made to open a municipal dispensary in St. Paul. The City and County Hospital already provides about twenty-five beds for venereal disease patients. In Minneapolis the University Dispensary has adequate clinics for syphilis and gonorrhea, and the University Hospital has recently set aside twelve beds for these patients. In Duluth a clinic will probably be established under the local health department. Arrangements have been completed in these three cities for examination of all police court cases, and their quarantine and treatment when necessary.

In connection with these dispensaries, and cases placed under quarantine from the courts, there was distributed up to March 31, 1918, in California 1,660 doses of arsphenamin. This was distributed to thirty-two different dispensaries or health departments, and was given to 393 patients. For the most part, these were a class of people who under former conditions would have received no treatment. In view of the fact that these patients received an average of more than four doses of arsphenamin within this rather brief period, it is felt that a piece of work worth while has been accomplished. These patients also received mercury by inunction or injection.

PRIVATE PATIENTS

Adequate provision must be made for the treatment, and especially for the control, of private as well as indigent patients. This necessitates the passing of laws or rules and regulations, by the state board of health, under which these patients can be required to take the necessary amount of treatment.

There should be a system of notification identifying in some way those persons venereally diseased, and providing for a report of the name and address of the individual who does not so conduct himself as not to endanger others. The health officers should be responsible for the control of these individuals when they are reported. A rule should also provide for parents and guardians being responsible for the compliance of minors. In all cases reports are strictly confidential. Many physicians believe that notification is bad, as it is thought that it will have a tendency to drive patients away from them, and into the hands of druggists and quacks. The public in general, and patients in particular, should be informed carefully of the confidential nature of these reports, and that so long as they as patients continue under treatment and conform to the necessary rules and regulations, their names and addresses need not be divulged, nor will there be any difference in the relationship to their physician on account of this work.

California has had for several years a law requiring the reporting of these cases by number, but no definite effort ever has been made to enforce it. Since the campaign was undertaken, however, their reporting has increased to more than three times the amount for the previous year. In Minnesota we are just preparing to inaugurate this work by circularizing all the physicians and asking their support for the government program. Many states in which reporting is now going on report the complete cooperation of the medical profession.

So far as we are concerned with the druggists, rules should be passed which will prevent counter prescribing, or the sale of any preparation or nostrum in the treatment of syphilis or gonorrhea. This sort of treatment means the loss of a considerable amount of time to the patient, and also in most cases it means that the patient, when finally presenting himself to a physician, has a chronic, difficult case, rather than an early case in which proper treatment can be very much more successfully given.

There is also a point in connection with this which distinctly concerns the Army and Navy, and indirectly also the civil population, and this is the treatment of soldiers or sailors by drug stores. This is to be condemned for two reasons. In the first place, on account of the men themselves getting inadequately treated, and in the second place, because it prevents the Army surgeon from placing these men under control, since the rules in the Army and Navy are that no such infectious patient be granted a leave of absence from the camp, and in that way any infection to the civil population is prevented.

By preventing the advertising of quacks, and by proper education of the people, it would seem possible to put the obvious quack or faker out of business. But it will be rather more difficult to restrain certain otherwise reputable physicians who persist in practically labeling themselves "quacks" so far as venereal diseases are concerned, by agreeing to cure these diseases quickly for stated fees. Generally speaking, the control of these patients who go to private practitioners depends almost entirely on the hearty cooperation of the medical profession, both individually and collectively. It is to be hoped, particularly at this time, when the value of this work to the federal government is so great, by reducing the disability among soldiers and sailors, both present and prospective, and among the vast army of industrial workers, that all physicians will pledge themselves to this cooperation.

EDUCATION

The systematic education of both laity and physicians as to the danger of these diseases, to their prevalence, and to the needs of adequate treatment, is the most important of any single method of attack. This should be directed along two distinct lines. In the first place, a campaign should be undertaken to get information to both laity and physicians from the disease standpoint. This should include lectures, distribution of pamphlets, setting up of placards in public comfort stations and other appropriate places, and various other means of publicity. Lectures should be given to various groups of men and women, and to county medical societies, both relative to the diseases and to the program for their control. A pamphlet on the treatment of these diseases should be furnished to physicians, as well as one containing information and instructions to be given patients. A carefully planned exhibit and stereomotorgraph with proper slides may also be used very successfully in various communities.

The other part of the educational work is directed toward those who in turn will be teachers, and is not limited in its scope entirely to venereal diseases. Courses should be arranged for in every state university, and in all normal schools. These courses should cover biology, psychology of sex, sociology, sex hygiene and venereal diseases. Courses should be given in medical schools with particular reference to the public health side of the problem. Courses should be given to hospital, public health and school nurses. Under the educational department a course of study of sex education should be planned for parents' and teachers' associations. Communities should be stimulated to the further use of present recreational facilities. The need and the part this work plays in stimulating a normal sex life in the young should be emphasized. This is particularly a great need in the rural communities.

I believe one important detail of the educational work should be giving people to understand that something can be done if exposure has already taken place. This may be called early treatment, or prophylaxis, as one wills. Its value has been fully demonstrated by the Army; of that there can be no question; but there is the question as to how this information should be given. I myself believe such information should be given individuals at the time of their attendance to the hospital or dispensary, and that people should be urged to go to these places for advice; but I do not believe that the public in general is willing to have such information spread broadcast to the youth of the land, nor do I believe that it would be proper on our part to advocate the sale of a prophylactic package, since that savors of the very drug store treatment that we are attempting to discard.

In connection with the educational work in California, forty lectures were given in cooperation with the War Department's Commission on Training Camp Activities, which reached approximately 55,000 enlisted men. A limited number of lectures were given to certain groups of people throughout the state, and a definite campaign for work along this line has been outlined. A number of sets of posters furnished by the American Social Hygiene Society were placed in various Army and Navy camps. A stereomotorgraph with proper slides was purchased, and sent first to Camp Kearney, at that time the largest cantonment in the state, and from there to others in different localities. Approximately 2,000 placards with information on venereal diseases were distributed and placed in the latrines of the Army and Navy camps of the state. Approximately 1,600 were distributed and placed by local health officers. About 6,000 pamphlets on venereal diseases, and 5,000 on the modern treatment of syphilis, were distributed throughout the state during the six months' period.

In Minnesota we feel that our educational program is well under way in view of the time elapsed. During the past winter complete courses were given at the university, and at a number of the normal schools of the state. Dr. Ulrich, who has charge of this work, has given fifty-five lectures to approximately 10,000 people. A number of different pamphlets have been issued and are being distributed. An exhibit is being planned and a stereomotorgraph with complete sets of slides has been ordered. A copy of the War Department's film "Fit to Fight" has also been ordered and will be shown to all enlisted men.

CONCLUSIONS

The program as proposed, and as put into force by the War Department, has already been proved a success by the fact that our armies now have the lowest venereal disease rate of any army in the field, and for weeks the rate of the expeditionary forces has been only about half that formerly averaged by our Regular Army. The program as proposed for civilians is along the same lines and is intended to be carried out in cooperation with the Army and Navy. There is every reason to believe that it will also be successful, particularly if it receives the support of the profession. There is a good opportunity for the private practitioner to show his desire to help by complying with all rules and regulations and by doing as much individual educational work as possible. The specialist who does not enter the Medical Reserve corps has an opportunity to serve at home by taking an active part in this movement, by lending his assistance with his special training, not only in working out problems, but by giving some time to dispensary work in his community.

There is need for the federal government to come to the state's aid in the way of finances just as England has done, and such legislation is now before Congress. With this assistance, the work will go on much more rapidly.

Emphasis should be placed on the educational work, particularly in the medical schools, as the people at large depend on the physicians for information concerning these diseases, and unfortunately the majority of the medical profession have little idea of the modern conception of sex hygiene or the public health point of view of the problems of prostitution and venereal diseases. This is due primarily to a lack of teaching of these subjects in the medical colleges.

A well rounded program for combating venereal diseases must take cognizance of every factor that enters into their spread. Any attempt to limit the work to any one field will fail, just as medical efforts at reducing venereal disease through attempted regulation of prostitution has always failed. In its last analysis we must agree with Surgeon-General Gorgas that venereal diseases depend on sex immorality for their spread; and until we do away entirely with immoral sexual relations, we cannot do away entirely with these diseases.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. PUSEY, FORDYCE AND IRVINE

Dr. John E. Lane, New Haven, Conn.: The work which Dr. Pusey and his associates have done has already given such definite results and has been demonstrated to be of so great value that it cannot help assisting in the adoption, by other states, of the plan suggested by Dr. Irvine for the prophylactic measures which he has already introduced in several states. It is interesting to know that the value of the prophylactic measures adopted in our Army has already been recognized in France. You may remember that Fournier, in 1901, established the Society of Sanitary and Moral Prophylaxis in Paris, and planned prophylaxis on the lines that we have adopted. The measures suggested have never been taken very seriously by the majority of French physicians. A short time ago Sabouraud visited our army camps in France and gave a most flattering report of the result of the prophylactic methods used by our Army. He at the same time deplored the fact that the French, who first originated the plan and methods of prophylaxis, had to be shown how to put them into operation by the Americans.

We are all indebted to Dr. Fordyce for his insistence on the need of examination of the spinal fluid in cases of syphilis and for his persistence in demonstrating this need. We are also indebted to him for his persistence in demonstrating the need for organized hospital and dispensary facilities for the treatment of syphilis. It must be a cause of gratification to him to see that his efforts are beginning to bear fruit.

Dr. Irvine has been one of the leaders in the movement for getting the venereal diseases under the control of the state health authorities. The value of his work is best shown by the fact that several states have adopted plans similar to those which he has put into execution. I am glad to say that my own state is one of them.

Dr. John H. Stokes, Rochester, Minn.: I have myself been converted from a stand of opposition to intraspinal medication to the point where, while not an enthusiast, I am prepared to admit that at the hands of a man like Dr. Fordyce it is possible to produce results which cannot be duplicated by the conventional methods. On the other hand, I still feel that intraspinal therapy is a final rather than a first resort and that it should not be undertaken by the tyro. At the hands of the profession at large intradural therapy has been sadly overdone. This, however, is by no means a reflection on the method, but rather on those who have let enthusiasm get the better of their discretion. The results mentioned by Dr. Pusey and Dr. Irvine have interested me greatly. My personal hope is that state programs, however excellent, will not be allowed to overshadow the need for a really national campaign against venereal diseases.

Dr. King Smith, Toronto: Men with well-marked psoriasis should not be taken into the Army. They live in huts and tents with other men and often such men are put down as syphilitic and their life is miserable. It is the same with many other diseases. Many cases of typical psoriasis and other diseases are considered syphilis, and it is hard to change the diagnosis. The soldier's pay is altered, as you know, and that man does not start in with a fair chance. I would like to suggest to Dr. Pusey that they think of the returned men. They will soon be sent back in great numbers with the loss of a leg or an arm and syphilis. The man cannot be kept in the Army, and you must find some way in which those men can be treated thoroughly in a civilian capacity. In Canada we have formed a league whereby these men can be gotten out of uniform but still receive care. The more you serve the more you will protect your other countrymen. You must give them every chance in this game, for they have given up everything for us, and we must protect them and when possible train the men not to put down syphilis against a man's name until he is sure of it. Get him back to the base hospital where he can have thorough treatment, and then make the diagnosis.

Many diseases have been put down to nervous origin. I found thousands of such cases soon after the evacuation of Gallipoli, where I happened to be. I saw only a very few irritated cases, never a lichen planus, and what struck me was the marked absence of nervous disease after going through that great campaign. The great thing I saw was the ecthyma group, which is often put down as syphilis. The men necessarily cannot change their clothes, the pediculosis is extreme and the ecthymoid conditions are very severe, forming great ulcers which look like tertiary syphilis, but are not. We sometimes do a routine Wassermann on a returned man, but I do not think this is justice to the man. If the man has not shown evidence of syphilis in the Army and you find the Wassermann positive, it goes down in the history sheet, he has to go down and take treatment, and if he refuses to do so it goes down on his chart and so becomes public property. The returned man, unless there are marked lesions, should be gotten out of the Army and in that way protected. If he is in the hospital his wife and friends come to see him, and everyone soon knows that he is attending a clinic for venereal disease if that plan of treatment is adopted. I do not believe in the long treatment of syphilis while the men are in the Army. If you can get the lesions cleared up, send them back to the trenches as soon as possible. They have as much right to be there as the healthy, sound men.

Dr. A. Schuyler Clark, New York: I have been in the Army for one year and up to the present time have never given a pink pill. My work has been entirely administrative and has consisted for nine months of medical administrative work in a division and three months in a base hospital, so I am inclined to look at this question from the point of view of efficiency in the Army and of administration. The point of putting a case of venereal disease in the hospital has two sides. There is no question that every acute case should be in the hospital, but there is a very decided objection to keeping them in the hospital too long. There is a great tendency for some soldiers to get "hospitalitis" or become hospitalized, and once that has happened it is extremely hard to get them interested in an organization again and anxious to go to the front, as all our soldiers are. A member of our organization is doing most efficient work at Camp Grant. I refer to Major W. L. Baum. The idea of getting venereal patients out of the hospital and having them treated by their organization is being urged by him. It is being tried out at the present time at the Depot Brigade at our cantonment, where they receive the new men coming directly from civil life. A venereal infirmary is being established there for the treatment of venereal patients in order that they may be gotten out of the hospital as soon as the acute stage is over. I am convinced that from the point of view of efficiency in the Army this plan is along the proper line. I believe that soom a division infirmary will be organized and there it will be important for an experienced venereal surgeon to teach the treatment of venereal diseases to the regimental officers of the detachment, requiring at least one regimental officer to report at this venereal infirmary and learn how to take care of venereal cases. I think that will be a future development in the Army. It is now being put into effect at Camp Grant. These soldiers do not wish to become hospitalized. I should like to tell you how appreciative the officers at Camp Grant are relative to the efforts being made to prevent prostitution in Rockford. I have never seen a cleaner city than is Rockford. It is rare to find a so-called new venereal case. The women of Rockford meet the trains and a questionable woman is approached by these women and advised that she had better return where she came from. If this is not effective, supervision is kept over her, and sooner or later she is put in jail or gotten out of town. This has a splendid effect on the cantonment in the prevention of venereal disease. There is no question about the effectiveness of prophylaxis. Another element which I consider of very great importance is the abstinence from alcohol.

Dr. Henry R. Varney, Detroit: Dr. King Smith was speaking of the proper treatment of the returned soldier, but I think there is another point, and that is the duty we owe to the returned soldier's family. I should like to ask what is being done to prevent these returned soldiers from infecting their wives and children with gonorrhea and syphilis.

Dr. Fred Wise, New York: As I have the good fortune to be one of the few men in the room who is associated with Dr. Fordyce, I will confine my remarks to a discussion of his paper. In his recent writings his aim has been a campaign of education for the physician more than for the layman. The question of neurosyphilis has occupied his time for several years, but in spite of the fact that he has an overwhelming supply of data to present it may surprise you to know that in our city of New York many doctors not only do not follow his precepts in the treatment of neurosyphilis, but actually decry the value of spinal punctures. Dr. Fordyce's reports are based not on imagination, but on careful scientific data which have accumulated after years of hard labor. Naturally I can appreciate the work which he has presented to you today, because I have before me every day the results of the spinal treatment of neurosyphilis. If the handwriting on the wall be interpreted correctly, every doctor, specialist or practitioner will not only have to master the subject of spinal puncture in every case of syphilis, but also the treatment of neurosyphilis on the lines laid down by Dr. Fordyce.

Dr. James Herbert Mitchell, Chicago: Many of the criticisms of intraspinal methods are incident to the dangers of that treatment. The original Swift-Ellis technic was designed for those cases which did not respond to the intravenous method. In our work we have limited our cases to those which did not respond to other treatment. The criticism which Dr. Stokes brings against the method will apply equally as well to the intravenous method. We have all seen a great many cases which have been markedly mistreated with the intravenous technic. That is not a criticism of the method, but of the clinician. During the past year I saw a patient in the dispensary who had had eight intravenous treatments. She had a hemiplegia and intense headache, which was not in any way relieved by intravenous injection. Spinal puncture showed 1,000 cells per cubic millimeter. One intraspinal injection of a large dose of undiluted serum gave her relief from the headache, and two further treatments relieved practically all the objective as well as the subjective symptoms.

Dr. Loyd Thompson, Hot Springs, Ark.: I wish to mention one or two things in regard to venereal prophylaxis in the Army which Dr. Pusey did not touch on, the enlisted man on furlough and the officer on leave of absence. I found that 8 per cent. of our men who contracted the disease did so while on furlough. We are not able to control their actions on those occasions, and they have no prophylactic material with them. It is my idea that it would be a good plan to furnish all men who go on furlough with a prophylactic kit of some sort. A man may go on pass one night and indulge himself and come back and fail to take the prophylaxis. He will go on pass again the next night, will not indulge himself, but will take the prophylaxis. He is within the law, so far as the Army regulations are concerned, and we have no way of knowing when the infection occurred.

In the matter of treatment: As long ago as last October I advocated establishing dispensaries in the divisions. Our division surgeon did not approve of it and we did not get as good results as we might have. We have now established a division dispensary which will take care of all ambulatory cases of venereal disease.

Dr. M. Scholtz, Cincinnati: In discussing sanitary control of venereal diseases we must differentiate clearly between the military and civic aspects. The military problem is so thoroughly and efficiently controlled by the federal government that we, as physicians, have no cause for anxiety as to the results sought for. The civilian problem is infinitely more difficult and complex. We should realize that the main reason why the venereal problem is so difficult of solution is because venereal diseases are social and secret. The medical profession as a body cannot render a greater service to society than by educating and molding its mind in this direction. When we have accomplished this our difficulties will largely cease. I believe, in this sanitary crusade of social hygiene, we should rely more on the educational campaign and more liberal attitude in the matter than on the oppressive legislation or on the raids on shady hotels. We should not judge the effectiveness of our clean-up efforts by the number of arrested women of ill repute. The effects of these measures are always transitory and local in character. We all know that these undesirable female characters, when driven out of one city, land in another community. We simply transfer our burden temporarily to our neighbors. From this viewpoint it is high time for the medical profession to urge the government to organize a national commission for the study of venereal diseases from every possible angle—medical, social, educational and economic—a commission which would insure a concerted action on the national scale and rational methods of solution.

Dr. E. H. Martin, Hot Springs, Ark.: Referring to Dr. Brown's paper, I wish to call attention to one factor which may have led to error; that it, that his experiments were made on rabbits with the initial lesion. Any one who has treated many cases of chancre must realize that the chancre is the most resistent of all syphilitic lesions to treatment until you come to the cerebrospinal colonies. Many organisms reside in the chancre, many of them in an unkillable stage, and the drug does not have the effect on them that it does on the ordinary forms of spirochete. Very often an indurated lump will remain at the site of the chancre for weeks after healing; very often ten doses of ordinary arsphenamin have been given before such a lump would soften. I believe if the experiments could be carried out on animals in the secondary stage, after the chancre had softened, they would be more valuable in determining which of the drugs is most curative.

Dr. Franklin R. Wright, Minneapolis: If we may believe the writings of Havelock Ellis, there has been only one race of people discovered who did not have prostitutes, and they had polygamy. The question simply comes down to one of sex; the male has strong sexual desires, while the female has maternal desires. Applied to the human race, the male is a natural Mormon and the female is not. It is simply a matter of sex all the way through. One of the leaders on sex questions has stated that if a man of 35 brags that his will is so strong that he has never had intercourse, that man is boasting of the weakness of his sexual powers instead of bragging of the strength of his will power. The question is, Are we willing to teach the general public that all unmarried men have intercourse, and that the state has cured all persons having illicit intercourse of contagious disease and made fornication as safe as possible? Are we ready to go so far as to teach the public that there are measures which they can take by which the chances of infection are reduced to the minimum? If we are ready to teach the young boys and girls these things, well and good. The Army is a different proposition. It is a well-known fact that the men who do the heavy physical work are not the ones that have strong sexual desires. The men who do the mental work and live sedentary lives are the ones who have the strong desires. Army life is a fairly active life.

There are reasons why the Army shows great diminution in the amount of venereal disease. All these cantonments are in small communities. The number of prostitutes in any community is in proportion to the number of unmarried males. More than this number cannot find lodging suitable to their vocation. This is the situation at Rockford, Ill.; Battle Creek, Mich.; Camp Kearney at San Diego, Calif., and other places. At Camp Custer, Mich., between October 1, 1917, and December 15, 1917, there was only one young man admitted to the Base Hospital who had acquired his infection after entering the Army. There were no prostitutes at these places, except a few to take care of the needs of the unmarried men among the 30,000 people living in Battle Creek. This reason will apply to Camp Kearney, Calif., the same as at Camp Custer, Mich.

Dr. Wade H. Brown, New York: In experimental therapy we have to take such conditions as we find them and make the best use of them. As to the use of the rabbit for experimental purposes, well developed and enduring primary lesions are relatively easily obtained, while there has been a great deal of discussion as to the extent to which a true generalization of the infection with secondary lesions follows a local inoculation. In recent years we have found that a true generalized syphilis does occur in the rabbit in many instances and that secondary lesions may appear even as late as sixteen or eighteen months after inoculation, but such lesions may be very transient and, as a rule, are much more easily influenced by treatment than the primary lesions. Further, when treatment is instituted during the primary stage of the infection with consequent healing of the initial lesions, if a true cure has not been effected, secondary or generalized lesions may appear later in a considerable number of animals and this is particularly true of certain drugs, as instanced by the results reported with various arsphenamin preparations. For these and other reasons which we might mention, it seems better as a routine procedure to treat experimental animals during the primary stage of the infection and to rely on the subsequent development or absence of generalized lesions during some four to six months than to treat the more transient and more easily influenced secondary lesions. Under the circumstances, this is all one can do, as a rule, and the results obtained from such experiments furnish reliable presumptive evidence as to the therapeutic action of the drugs used.

Dr. William Allen Pusey, Chicago: I would like to call Dr. Wright's attention to the fact that the reason there are not more women in Rockford and Battle Creek is not because there are not more prostitutes that might be available for these districts, but because it is a part of the Army work to keep them away.

Regarding the question about what to do with cases of venereal diseases after the war, this is undoubtedly very important, but so far there has been considerable to do to take care of the venereal cases during the war, and not much has been done as yet toward the care of them after the war. The protection of the family against venereal disease while the man is in the Army is pretty well taken care of by the fact that these men are not allowed to get away.

Regarding the percentage of venereal disease, the Army program has taken some pride in the fact that it has not been an unworkable program. I do not mean that it is ideal, but only a fair standard at the present time.

Dr. John A. Fordyce, New York: I had no intention of presenting the subject of intraspinal therapy in neurosyphilis, but as this has been touched on by several of the gentlemen I will briefly refer to it. In order to obtain results by the method in question one must have a very clear conception of the various conditions present. In other words, indications for or against this therapeutic procedure are afforded by the results obtained from an examination of the spinal fluid. Early meningitis may occur before, during or after intensive treatment. These cases can best be controlled by intraspinal injections. In tabes, with a relatively high cell count and positive Wassermann, if the degeneration be not too far advanced, we can anticipate further degeneration, relieve the pains and cure the crises in the majority of cases. In optic atrophy, with the preservation of one half or one third of the vision with positive findings in the fluid, we can arrest in the majority of cases the further progress of the atrophy.

Many neurosyphilis patients come to me in my private work and in the clinic who have had a large amount of treatment of arsphenamin and mercury. It is useless to continue the ordinary methods of treatment in such cases. They are treated intraspinally if the indications afforded by the spinal fluid examination point to an involvement of the meninges. Many cases of disseminated cerebrospinal syphilis which have not been cured by ordinary treatment have been cured or greatly benefited by the method in question. In the past five years we have treated about 170 cases of various types of neurosyphilis and have obtained a negative cell count and negative Wassermann in 2.0 c.c. of fluid in about 30 per cent. of the cases. We do not consider the patient cured until we obtain a negative Wassermann with the larger quantities of fluid. As to the benefit to be expected in paresis we cannot say as much. There are, however, borderline cases of meningo-encephalitis which simulate paresis and which have been cured. In the routine examination of the spinal fluid in the various types of neurosyphilis we frequently meet with patients who give a four plus (++++) Wassermann in 0.2 c.c. and a paretic colloidal gold curve. Although these cases presented no stigmata of degeneration, we consider them potential paretics. In these cases treatment probably delays for a long time the development of the later degenerative stage.

Dr. Harry G. Irvine, Minneapolis: In regard to the returned soldier, the federal government should notify the state boards of health of any diseased man coming into their district. Where the program which has been suggested is enforced it would be possible to have these cases taken care of in their dispensaries. This program provides for this very thing and not only for the care of the returned soldier, but will also protect his family and the community as necessary. I am sure that the Surgeon-General's Office has gone into this matter and that it will be given serious consideration. The relationship of prostitution to venereal disease can hardly be settled in two or three minutes' discussion. It is possible to do away with commercialized prostitution, which is not in business to take care of the demand but to create a demand, and this can and should be done away with. So far as control of prostitution is concerned, it is worthless to institute any form of medical examination to attempt to make it safe. In any attempt at regulating prostitutes it has never been possible to register more than 10 per cent., and it is worthless to adopt any program which can be applied to those registered and not to the others, who are in the majority. So I cannot see that it will ever be possible to make the prostitute safe, so far as venereal disease is concerned. I think that the habits of the male have a great deal to do with the amount of intercourse. If a man is in the habit of doing without for a long time he can do so very nicely. The question of alcohol, whether a man is working or not, and the nature of his work all enter into it very largely, but as time goes on and we have better sociological conditions we will likely develop a race of men who will get along with much less intercourse than has been the case in the past, even if such a thing is not the case at present.

The question of making prostitution safe brings up again the segregated district, and that has been shown to be an absolute failure, so far as venereal disease is concerned. Many of the best authorities have gone on record, publicly stating it as their opinion that any attempt at medical regulation has always been a failure so far as reducing venereal disease is concerned. I think that until we are as well informed as those men are it is hardly good form for us to question the statements which they make.

THE QUESTION OF OPERATION IN GUNSHOT ABDOMINAL WOUNDS *

JOSEPH RILUS EASTMAN, M.D.
INDIANAPOLIS

The study of gunshot wounds of the abdomen deals with one of the most interesting chapters of the major wounds of war, especially by reason of the numerous controversies relating to a general plan of treatment of abdominal wounds. Certainly the present war has developed important advances in this department of surgery.

In previous wars it was held as dogma that gunshot wounds of the abdomen should be treated expectantly and conservatively, as distinguished from the teaching of prompt operation in civil practice. At the present time, it may be said that the weight of opinion is in favor of applying in military practice the civil method of immediate operation in all penetrating wounds of the abdomen wherever the favorable conditions of civil practice can be provided. These essential conditions include a skilled operator, trained assistants, a sufficient armamentarium, an aseptic environment, and the time in which to operate. Practically all agree that it is better to await the establishment of these conditions before attempting to operate.

It is likely that the best explanation of the improved statistics of operation in this war is to be sought in the favorable conditions of trench warfare, the battle lines being in the main more stable than in former wars, and allowing of better preparation for operating near the front.

Chalier and Glénard[1] express the view of most war surgeons in all armies when they say that expectancy is a "snare and a delusion." It is permissible only when twenty-four to forty-eight hours have elapsed since the injury, when operation could do no good. In this event, they advise that no food should be given and the man should not be sent back any distance until after six weeks.

Notwithstanding the fact that the experiences of the present war have modified the old views as to the advisability of abstention in abdominal wounds, there still remains, notably in France, a rather sharp division between what are designated the abstentionists on the one hand and the interventionists on the other. The former group bases diagnosis of penetration and perforation, as well as treatment, on the evolution of symptoms; the latter group makes the complete diagnosis by laparotomy, applying appropriate surgical treatment immediately or within the first few hours. Unfortunately, the most experienced surgeons occasionally find more or less difficulty in diagnosticating penetration and perforation before operation, and all are, of course, opposed to precocious operating in nonpenetrating wounds.

There is not always present an aperture of exit, in which case it is difficult to determine the course of the missile. All missiles may ricochet. I have witnessed wounds in which, if the missile had traversed the shortest route between the two openings, there would have been perforation of many vital organs and structures, and yet there was no serious injury.

There are a few recognized rules to follow; for example, the closer together the wounds of entrance and exit, the less the chance of penetration. And Rochard[2] declares that if a wounded man does not cease to complain of abdominal pain, a perforation is almost certain. Rochard also says that if a patient passes gas at the anus, there is no perforation.

All rules fail sometimes, with the exception of these three which prove the existence of perforation: escape of bowel contents from the wound of entrance or exit; protrusion of perforated intestine at the wound, and passing of the missile by the anus. Schwartz and Mocquot[3] describe four cases of perforation showing no signs. I have observed the case of a man with perforating wound of the abdomen who continued active duty for several hours after receipt of the wound, having no knowledge of the injury. Six hours after injury, the abdomen at operation was filled with blood.

Among the common signs of perforation are pain; vomiting; hiccuping; costal breathing, due to immobility of the diaphragm; the syndrome of shock; boardlike rigidity of the abdomen (*ventre du bois*); retraction of the testicle to the external abdominal ring; change in shape of the abdomen, for example, the "ventre bilobé" from meteorism; emphysema as in colon wounds; tympany; temperature changes, etc. To these may be added the symptoms of intra-abdominal hemorrhage. A true interventionist does not, of course, await the appearance of all these symptoms, since one may suffice to determine the propriety of operating.

CONDITIONS DETERMINING OPERABILITY

Among the deciding criteria which determine the advisability of operation are the following:

1. The kind of missile. A smooth undeformed bullet as a rule makes a small canal in the abdominal wall and a small easily sutured opening in a hollow viscus unless the shot be tangential to the intestine. Such a smooth bullet, however, usually produces an irregular laceration of a parenchymatous organ. The aperture of entrance being smaller and more clear cut than the aperture of exit. Irregularly deformed bullets naturally produce larger and more ragged wounds than do smooth ones. For example, the fragmented nickel or steel mantle partially split off and projecting from a lead center bullet may do great damage. Large

[3] Schwartz, Anselme, and Mocquot, Pierre: Rev. de chir., 1916, **51**, 56.

grenade fragments do not as a rule penetrate deeply, but often cause extensive crushing and laceration of the abdominal wall. Small grenade fragments often do very little injury, but may produce a deceptive wound; that is, the wound of the abdominal wall may seem insignificant, whereas the intra-abdominal injury is extensive and serious. Shrapnel balls often remain impacted in the abdominal coverings. They are of low velocity and usually retain their smoothness and rotundity and do comparatively little damage to viscera, considering their large size. They rarely completely traverse the abdomen. Shrapnel wounds are usually infected because the low velocity missiles push into the clothing, whereas the small, high velocity rifle bullets cut clean, small wounds and do not often carry in fragments of the clothing.

2. The length and character of transportation required to bring the patient to the place of operation. Koerte places the limit of operability at twelve hours, and Chalier and Glénard at twenty-four hours, and the records of all show that the operative mortality percentage rises rapidly with each hour during which operation could be done after the subsidence of shock.

TABLE 1.—STATISTICS OF ABDOMINAL WOUNDS TREATED BY THE ABSTENTIONIST METHOD

Stern	50	46
Tartois	8	8
Vignard	11	2
Weiss and Gross....	57	49
Total	983	760

Proportion of mortality, 77.3 per hundred.

3. The stability or nonstability of the place of operation determining whether the patient may require transportation soon after operation.

4. The factor of time, that is, the question as to whether time can be given for the operation without neglect of other wounded.

In any case, before operation is undertaken, the interventionist excludes simple, nonpenetrating injury of the abdominal wall. Likewise, he considers the question of whether conservative treatment, under the circumstances relating to the wound, the patient's general state and surrounding conditions would not be better.

INTERVENTION VERSUS ABSTENTION

At the beginning of the war, nearly all surgeons were abstentionists. For example, Aug. 10, 1914, in an address to the Academy of Sciences, Delorme advised against intervention, saying that experience in the Transvaal and in the Manchurian and Balkan wars justified the expectant plan, but the records of the interventionists are better in this war, as shown in Tables 1 and 2, taken from Chalier and Glénard.

It should be noted that the interventionist verifies his diagnosis of perforation, or, in the French nomenclature, penetration with injury of the viscus; whereas, the abstentionist may designate as perforation cases some which are not perforative. M. Chevassu, who was an abstentionist, not by choice but by unfavorable circumstances, had only twenty-seven deaths in eighty-five penetrating gunshot wounds, but according to French writers, many of these were doubtless cases of simple penetration without any injury of an important viscus. Moreover, the interventionist's deaths occur promptly and are counted against him, whereas the abstentionist's deaths are often late, as from fistula, and are not counted.

Total	890	530

Proportion of mortality 59.5 per hundred.

In support of intervention, the Interallied Surgical Congress of last March expressed the view, which is the most authoritative available, that all intestinal wounds should be treated by laparotomy, with suture. Most surgeons reserve the suprapubic buttonhole drainage, which the French call the operation of Murphy, and which the Germans ascribe to Payr, for cases of simple penetration without perforation. Payr advised that in all penetrating abdominal wounds an incision be made promptly above the symphysis for drainage.

Chalier and Glénard treated fourteen of their thirty-nine cases of abdominal gunshot wounds with simple drainage of the pouch of Douglas with intraperitoneal injections of ether and oil of camphor. They also injected oil of camphor subcutaneously and employed the Fowler position. There were ten deaths among the fourteen patients. None of the patients were operated on within ten hours after injury and some were operated on as late as the fourth day.

TABLE 3—RESULTS OF SUPRAPUBIC DRAINAGE IN FIFTY-FIVE CASES

Bouvier and Caudrelier:
16 operated on in less than 3 hours, 8 deaths, 8 cures.
11 operated on in less than 5 hours, 5 deaths, 6 cures.
2 operated on in less than 6 hours, 2 deaths, 0 cures.
Lapointe:
14 operated on in the first 7 hours, 8 deaths, 6 cures
12 operated on after the first 7 hours, 12 deaths, 0 cures.

Table 3 shows the results of simple suprapubic drainage in fifty-five cases.[2]

What may be called the internationally accepted treatment of patients not to be operated on consists in rest in the recumbent position with shoulders raised and knees flexed. This position relaxes the abdominal musculature and adds to the comfort of the patient. No attempt should be made to move the patient unless the move is unavoidable, nor should he be permitted to move himself. If he is moved before the operation, the Fowler position should be maintained during transport. Food by the mouth should be interdicted and water likewise should be forbidden, unless neither nausea nor gas is present. A teaspoonful of water at intervals of fifteen minutes may be given by mouth to moisten the dry mucosa. Food and water may be given by the bowel in the case of lesions of the small intestine or the stomach, the common sites of perforation. Opium should be given to control pain whether the operation is to be done or not. Shock is to be combated by heat, and by physiologic sodium chlorid solution administered hypodermically, by rectum and by intravenous infusion.

MORE COMMON INJURIES OF THE VARIOUS INTRA-ABDOMINAL ORGANS

Gunshot injuries of the stomach are of frequent incidence. Perforation of the stomach when it is full is more serious because of the escape of the contents, than when the organ is empty, notwithstanding that the openings made by the missile are smaller, all things being equal, when the stomach is distended (Landois). The commonest injury is that in which the aperture of the entrance is on the anterior wall and the wound of exit on the posterior wall. This, of course, may be reversed. Both openings may be on the anterior wall, or on the posterior wall. In the latter case, the stomach contents will empty into the lessser peritoneal cavity.

Landois has called attention to a frequently occurring phenomenon, namely, the outpouring of stomach contents into the lesser peritoneal cavity through a wound of exit in the posterior wall, while the wound of entrance on the anterior wall discharges no contents at all.

Little value attaches to the symptoms of hematemesis in stomach wounds as it is rarely present. Wounds of the anterior stomach wall are, as a rule, easily found and readily closed. The wound on the posterior wall is not always easy to find nor is it easy to close by suture. Through a large opening in the gastrocolic omentum, the lesser peritoneal cavity may be mopped free of blood and the stomach contents and the posterior wall inspected. Occasionally one can find the posterior wound with the finger but cannot bring it into view for closure by suture. In such a case, drainage without suture is safer than blind and awkward attempts to repair the wound. An experienced surgeon, however, will not often be driven to forego the suture of any stomach wound.

Pauchet has advised approaching the posterior stomach wall through an opening made by separating the greater omentum from the transverse colon along the line of the insertion of the omentum to the intestine. I have found that this method provides excellent exposure. It is very easily carried out.

Of all the hollow viscera, the small intestine is the most frequently perforated. Horizontal close range shots with the wound of entrance near the umbilicus produce most perforations. There may be wounds of entrance and exit in each wounded coil of intestine or a single opening may be present, the result of a tangential shot. As a rule, the openings are present in pairs, the wound of exit being the larger and accompanied by more marked extrusion of mucosa. Irregularly deformed nickel or steel-jacketed bullets or grenade fragments may entirely divide the small intestine. Of great practical importance are the wounds establishing communication from the intestine lumen to the space between the peritoneal laminae of the mesentery produced by tangential shots of the small intestine at its mesenteric attachment. These may be overlooked.

A few hours after perforation of the small intestine, the neighboring peritoneal surfaces become covered with plastic exudate, which in the case of small wounds, for example, those from minute grenade fragments may effectually prevent further escape of intestinal contents and occasionally lead to spontaneous cure. The benign, walled-off abscess is unfortunately a much less common sequel of perforation than is general peritonitis.

The comparatively hopeful outcome of injury of the large intestine has been ascribed to the fact that the walls of the large intestine are thicker and the wound is partially closed by the greater amount of tissue involved in the perforation. An interesting point is that wounds of the small intestine higher up are more likely to be associated with injuries of other vital organs than are wounds of the large intestine. Many surgeons of the present war support the view of Landois that if we eliminate from consideration associated lesions of other organs, infection from injury with escape of contents of the large intestine is more serious than that following injury of the small intestine. The contents of the cecum and ascending colon are rich in bacterial flora of virulent character, so that comparatively few patients with perforation of the colon survive even when promptly operated on. A smooth rifle ball or a small grenade fragment may produce a small wound of the colon which more or less perfectly closes itself by contraction of the muscularis and the sliding of the intestinal coats. In such a case, the escape of contents being slight or nil, the chance of recovery is good if the operation is performed promptly.

Retroperitoneal wounds of the colon are often overlooked, especially in fat individuals. The presence of intraperitoneal hematoma and gray or brown-gray discoloration of the peritoneum with edema or gangrene in the neighborhood of the wound are valuable signs, though not always present. Retroperitoneal wounds of the transverse colon may elude search until the lesser peritoneal cavity is opened.

Extraperitoneal injuries of the rectum nearly always recover though the convalescence may be prolonged because of the development of fistula, cellulitis or septicemia. On the other hand, all injuries of the rectum which establish communication with the peritoneal cavity are to be regarded as serious.

Wounds of the kidney are, as a rule, accompanied by injuries of the intestines. If there is no evidence of perforation of the intestine, the kidney injury should be treated conservatively. Even in cases of extensive hemorrhage from a kidney wound, the treatment may well be conservative unless the case can be brought to operation very early and the hemorrhage is really threatening. Uncomplicated injuries often heal promptly. If the renal vessels are divided or great destruction of the kidney has occurred nephrectomy is required. As a rule, however, it may be stated that rifle bullet wounds of the kidney are best treated by rest and opium. Occasionally, gunshot injuries of the kidney are followed by hydronephrosis requiring incision and drainage.

Wounds of the bladder rarely produce dangerous hemorrhage. The bladder contents are normally not infectious, but if emptied into the peritoneal cavity, cause more or less chemical irritation. Obviously, extraperitoneal wounds of the bladder are less serious than those which involve the peritoneal cavity. Hemorrhage into the bladder suggests an extraperitoneal injury of the bladder. An empty bladder suggests intraperitoneal injury of the bladder with escape of urine into the peritoneal cavity. The interallied conference declared for primary suture of intraperitoneal bladder wounds and for suture of extraperitoneal wounds as well. Inaccessible wounds are to be enlarged and drained. Cystostomy should be done in bladder wounds with urinary infiltration.

Intraperitoneal wounds of the bladder demand abdominal operation if conditions are favorable. If not, a retention catheter should be introduced promptly. Extraperitoneal wounds are best treated by continuous catheterization or by perineal section.

A clean-cut wound of the liver is rare. Lacerations are the rule. The wound of entrance is small, the wound of exit larger, and the bullet canal fusiform. Star shaped wounds are not rare. Hemorrhage is always present, the degree depending on the size of the vessels involved. Fortunately, the liver tends to tear and give way between the large vessels. Near the hilus, however, the danger of injury to large vessels is great. Liver hemorrhage often subsides spontaneously. Blood pressure is low and the bleeding may be controlled nearly always by pressure with gauze pads. In wounds of the liver communicating with the chest, hemorrhage is into the chest cavity, rather than into the abdomen, since intra-abdominal pressure is greater than intrathoracic pressure. If there be extensive laceration of the diaphragm, the liver tissue may be extruded into the chest.

Uncomplicated gunshot wounds of the liver require no surgical treatment unless there is serious hemorrhage. This hemorrhage may be controlled in nearly all cases by gauze packing, which is left protruding at the abdominal wound.

Combined injuries of the chest and the abdomen are not uncommon. Landois divided these into five groups as follows:

1. Abdominal injuries associated with perforation of the diaphragm and pleural space. Since the pleural space extends considerably farther down laterally and posteriorly than the upper level of the abdomen, horizontal shots may, of course, perforate both cavities. In such a case, stomach or intestinal contents, bile or peritonitic exudate may enter the pleural space causing pleuritis.
2. Associated injury of thoracic and abdominal organs. In a complicated injury of the lung and liver the patient may cough up bile, or as in one case observed by the author, may cough up a bullet entering the lung by way of the abdomen and the diaphragm. Empyema may occur as the result of such a complication. The heart may also be injured by bullets passing through the abdomen.
3. Wounds with great laceration of the diaphragm. In such a case, the liver or other abdominal organs may be extruded upward into the chest.
4. Tangential shots of the lower thorax with contusion of the liver or kidney.
5. Separate or multiple injuries of the chest and abdomen.

ABSTRACT OF DISCUSSION

Dr. Daniel N. Eisendrath, Chicago: The principles underlying the treatment of gunshot and stab wounds of the abdomen are essentially the same whether the work is in civil or military life. Dr. Eastman spoke of the combined thoracic and abdominal injuries. These are of a special class in which in civil practice the perforation of the diaphragm and injury of abdominal viscera are frequently overlooked because the men do not think of anatomic relations, that the diaphragm has under it a large proportion of the male abdominal viscera. For that reason we are accustomed to look carefully within the first six to twelve hours, examining the patient with perforating stab or gunshot wound of the chest almost every hour for evidence of abdominal injury. Especially in the last two years of the war there have been a relatively large proportion of injuries of the thorax, which have gone under the name of the open, or leaking pneumothorax. In these cases there is extensive laceration and destruction of the chest wall with injury to the diaphragm, to which Dr. Eastman has referred, and extensive laceration of the liver. Since the Battle of the Somme there has been more tendency to treat these injuries by early exploration. This can easily be done by reopening the edges of the thorax wound to see whether there has been perforation of the diaphragm or injury of the subdiaphragmatic structures. Dr. Eastman spoke of the signs of perforation. These are not different in war from those seen in civil practice, and it is the consensus of opinion among those of experience that when these are present, under no circumstances should a chance be taken, but that laparotomy or exploration of the wound be done at once. Rather should this be done many times without finding an intraperitoneal perforation than that a perforation be overlooked. Of these signs rigidity of the abdominal muscles is one of the most important in indicating beginning peritonitis. If that rigidity spreads within two or three hours, or has at the time of first seeing the patient spread over one quarter or half of the abdomen, take no chances, but do a laparotomy at once. Accompanying tenderness is also a very valuable sign of beginning peritonitis. A third sign is increase in the pulse rate. Leukocytosis is also a guide, because this may be present after effusion of blood into the peritoneal cavity, as it is in cases of infection. You do no damage by operating in a case presenting these signs. If the wound has not perforated the abdominal wall you have done no harm. If there has been perforation of the abdominal wall you are in a position to deal with the injury. The first surgeon to suggest the value of suprapubic drainage was Dr. Van Buren Knott of Sioux City, Iowa. Many recoveries from generalized peritonitis in the last five years have been attributed to suprapubic drainage. With a generalized peritonitis you might as well pass your hand over a patient as to expect suprapubic drainage alone to effect a cure. Unless there is repair of the injury in the early stages such drainage is an irrational measure. I do not think any of us will fail to remember the clinical picture of perforation of the upper portion of the alimentary canal or pancreas with the hypertoxicity which comes from the activated pancreatic secretion. A method I have found of value in examining for perforation is that of placing a loose catgut suture about the coil of intestine at the point of beginning examination. If you find no perforation in the small intestine, begin at the catgut suture and examine the large bowel in the same way. The suture thus marks the beginning and the ending of the examinations.

Dr. John Young Brown, St. Louis: For quite a number of years I have been an earnest advocate of early operations in the treatment of gunshot wounds of the abdomen. There are some points relative to diagnosis to which I should like to call attention. The simple penetrating wound is a wound that penetrates the peritoneal cavity and does not injure the solid or hollow viscera. The penetrating and perforating wound may be subdivided under two heads: 1. The penetrating and perforating wound, where the bullet injures only the bloodless portion of the gut. 2. The penetrating and perforating wound, where the bullet perforates the intestine and mesentery. This last type of wound is readily diagnosed, as it gives immediate symptoms—the symptoms resulting from hemorrhage. The other two types cannot be diagnosed without exploratory operation. I have seen many cases with multiple bowel perforations, perforations occurring in the bloodless portion of the bowel, which presents absolutely no symptoms suggestive of the seriousness of the injury. Again, I have operated in a large number of cases where examination of the wound of entrance would indicate perforation, and, after exhaustive search, I failed to find any injury. Early exploration should be the rule in all cases. Cases that give no immediate symptoms may have multiple perforations, and the failure to repair them will result in fatal peritonitis. In regard to the combined wounds involving the chest and abdomen, all such cases should be explored. We no longer hesitate to open the chest. A stab or bullet wound penetrating the chest brings on a pneumothorax, and resection of a rib in order to see if the diaphragm is injured can be done with perfect safety. If the diaphragm is penetrated, the same rule should hold good relative to abdominal section. I seriously question the cases that have been reported as having recovered from multiple perforations without operation. I am inclined to believe that the diagnosis was incorrect.

HEMORRHAGIC DEGENERATION OF MYOMAS AND THEIR RELATION TO SARCOMAS *

ARTHUR E. HERTZLER, M.D.
KANSAS CITY, MO.

By hemorrhagic degeneration of myomas is meant that condition in which spontaneous hemorrhage takes place into the substance of a myoma that has previously undergone a degeneration. Gebhard sought to indicate the essential degenerative character of the lesion by calling it a necrobiosis. The changes which underlie the condition consist of an obliterating endarteritis, hyaloid degeneration of the vessel wall and degeneration of the surrounding tumor tissue, with finally a free hemorrhage into the interstices of the degenerated tumor. The end-result of hemorrhagic myomas may be one of several: 1. The hemorrhage may become absorbed from the substance of the tumor, leaving only cholesterin crystals or small cysts. 2. More commonly the escaped blood lies for indefinite periods in a fluid state (Fig. 1), but the blood may clot, leading to vascularization and organization of the blood clot. 3. The hemorrhage may result in perforation of the capsule of uterine tissue covering the necrobiotic mass (Fig. 3). The escape of blood from such a perforation may cause profound irritation of the peritoneum, or even death from shock. 4. Finally, a rapidly developing sarcoma may develop from the hemorrhagic tissue. It is the last named condition that concerns us here.

It is necessary in seeking the relationship between these hemorrhagic myomas and sarcomas to examine the conditions that precede the hemorrhage and to study the changes that take place in the mass after hemorrhage has occurred.

Cullen long ago pointed out that most myomas show some evidence of hyaloid degeneration. In most tumors the microscope is required to discover it. These areas of degeneration when more extensive may involve the tumor tissue diffusely, or only that portion most remote from the vessels, while that lying nearest the vessels remains undegenerated or even shows evidence of recent proliferation. On the other hand, the tissue lying next to the vessel wall may be the part showing the chief degeneration (Fig. 5). This seems to be the type in which hemorrhage is most apt to occur. Associated with the hyaloid changes there is always a thickening of the vessel walls and usually a narrowing (Fig. 6), or even an obliteration of the lumen of the vessel (Fig. 7). Surrounding these vessels more or less extensive hyaloid or mucoid material is found. These areas may liquefy and form cysts. This is the most common degenerative change observed at the operating table. It is tumors showing such changes that are prone to bleed into their substance. What factors enter which excite a hemorrhage within such tissue cannot be stated. It is probably due to a progressive decrease in the resistance of the vessel walls until they are weakened to such a degree that they are no longer able to withstand the intravascular pressure. Accidents to the common source, however, must sometimes play a rôle, for in some tumors multiple foci of hemorrhage are seen.

Once blood has escaped, a series of phenomena are observed. In some tumors the blood remains fluid for long periods of time. The history may indicate that hemorrhage took place months before operation, yet these tumors are fluctuating, and, when cut into, much blood escapes. This fluid blood may be contained in compartments of varying sizes, or may infiltrate the tumor diffusely. This blood may or may not undergo spontaneous coagulation within the tumor or when exposed to the air. In most instances a part coagulates before the tumor is opened and part remains fluid. Usually bands of fibrin that have undergone some development form a network across the small pools of blood. Within this meshwork, red blood cells lie which have not undergone degenerative changes (Fig. 8). In some instances this tissue proceeds to a complete development of fibrous tissue, and a typical angioma results. Sometimes, on the other hand, the fibrin bundles remain as such, showing no tendency to go on to the development of fully formed fibrous tissue. It is in these specimens, usually those in which the hemorrhage occurred some time previous to operation, that the most interesting changes take place. In fresh hemorrhages, nucleated cells are observed that can be identified as leukocytes. These cells arrange themselves along the fibrin bundles noted above. In older specimens these cells are larger, the nuclei are ovoid, and the protoplasm is more abundant. In other words, they may be called endothelioid. The way these cells arrange themselves along the fibrin bundles seems identical with that observed in tissue cultures. I have often observed similar phenomena in the study of the healing of freshly made wounds. In some specimens a part of the tumor may represent tissue in this stage (Fig. 9), and another portion may show more positive evidence of sarcoma. Finally the patient may attest to the character of the tumor by dying of a rapidly recurrent sarcoma. The question of fundamental importance is the source of the nucleated cells from which the sarcoma develops. They seem to come from the blood stream, because in recent hemorrhages they are mingled in the proportions in which one would expect to find leukocytes. More convincing to me is the fact that in the healing of peritoneal wounds the cells seem to be native to the blood stream.[1]

* Read before the Section on Obstetrics, Gynecology and Abdominal Surgery at the Sixty-Ninth Annual Session of the American Medical Association, Chicago, June, 1918.

* Owing to lack of space this article has been abbreviated for publication in THE JOURNAL by the omission of the illustrations. The complete article appears in the Transactions of the section and in the author's reprints.

[1] A more detailed consideration will be found in Hertzler, A. E.: The Peritoneum, St. Louis, C. V. Mosby Company, 1918, 1.

Should it prove to be true that these cells, which are found along the fibrin bundles, are derived from the blood stream, one would be warranted in designating such sarcomas as hematogenic. These would then be placed in contrast with the more common type resulting from metaplasia of the myoma cells, which may therefore be called myogenic.

The hypothesis set forth above finds support in the genesis of sarcomas of other regions. Sometimes in tumors developing in fascias after a single blow, similar pictures are observed. The same thing is true of processes in the intestine wall which begin as inflammations and end up as sarcomas. Closely related are reactive processes which do not end in malignant tumors such as desmoids and woody phlegmons. The first group is exemplified by those tumors which arise following injuries to bone or fascial plains, and the other by sarcomas following inflammations of the intestine wall. The latter type so closely resembles indurative inflammations that a distinction is impossible.

The disposition of the hemorrhagic myomas to form sarcomas finds a practical application in the fact that they are always objects of suspicion. Whenever any of the evidence of hemorrhage or the changes which precede it are present, the prognosis must be made with a certain reserve.

ABSTRACT OF DISCUSSION

Dr. Emil Novak, Baltimore: The work of Dr. Hertzler is very interesting, but he has not given sufficient evidence that these cells surrounding the blood vessels actually become converted into sarcoma cells, as he believes. We ought to be very conservative in our interpretation of these findings. Very few myomas do not show hemorrhages. In these cases of hemorrhage with blood thrown out into the tissues we always get what might be called a foreign body reaction. Sometimes we even get giant cells. I recently saw a case of large ovarian cyst with what seemed at first sight to be giant cell sarcoma in the walls of the cyst. Closer examination showed these to be simply a reaction to an old hemorrhage. If Dr. Hertzler can show other pictures proving the transition of these cells into actual sarcoma cells we can accept his theory. Otherwise, I feel that it is without proof. It is curious to expect hemorrhage in myoma to predispose very strongly to sarcoma when it does not do so in other parts of the body. This suggestion looks rather unlikely, especially when we find hemorrhage in practically all myomas of the uterus. Every myoma of the uterus ought to be cut open before it leaves the operating room. Unfortunately, there is little clinical evidence to indicate sarcomatosis, the process taking place in only one nodule. It is a great mistake not to cut into all nodules; the one overlooked may be the one becoming sarcomatous. One reason for the unfortunate outcome in sarcomas of this group is that supravaginal hysterectomy is done. Dr. Cullen some time ago reported a case in which supravaginal hysterectomy had been done two years before and in which at the time of report the patient had suddenly gone into collapse with symptoms of intraperitoneal hemorrhage. A large mass had arisen from the stump at the site of the old operation. The old specimen was looked up in the laboratory, where it had been examined two years before, and in one of the nodules the typical sarcoma was found, having been overlooked at the time of operation. Kelly and Cullen collected 2,300 cases of myoma and a little over 1 per cent. (twenty-five) were sarcomatous.

Dr. Bertha Van Hoosen, Chicago: I may not be able to add any weight to Dr. Hertzler's paper, but I hope I will not detract from its value if I demonstrate a reverse process, i. e., malignant disease converted into fibrous tissue. A patient, who had inoperable adenocarcinoma of the cervix and who was suffering from hemorrhage, profuse and bad smelling discharge, much pain and general debility, was given 9 grains of emetin intravenously with no reaction, and at the end of two weeks the hemorrhage and discharge had entirely ceased and she was able to be up and do light work. A second dose of 9 grains was followed by a severe reaction and sudden death. No pathology was found to account for the patient's death, and a section taken from the part most involved by the carcinoma shows in the superficial portions an extensive fibrosis surrounding small groups of carcinoma cells; the deeper parts of the section show no evidence of malignancy.

Dr. Arthur E. Hertzler, Kansas City: I have tried to make it clear that in order to get the facts of this argument one would have to review a considerable number of cases, observing the various steps in their development. In the myomas I see there is hemorrhage in only a small proportion of the cases. This may be explained by the fact that I never use the retractor, and have no traumatism, except that done by the operator's hands. Fully 90 per cent. of the tumors we have had do not have blood in the substance of the tissues. The percentage of sarcoma in the tumors I see is just about four times that in Dr. Novak's experience. In order to get the run of the general argument one must familiarize himself with the structure of cultures in vitro, the appearance of the cells and the fibrin bundles as they develop. He must also familiarize himself with the development of fibrous tissue along the lines of recent development.

PAROTITIS FOLLOWING INDUCED ABORTION IN A CASE OF PERNICIOUS VOMITING IN PREGNANCY *

W. P. MANTON, M.D.
DETROIT

REPORT OF CASE

Some time ago I was called into the country by Dr. Sharpe, in consultation, to see Mrs. X., a primipara, aged 23, who was then in her thirteenth week of pregnancy. Vomiting had begun on the eightieth day following the beginning of her last menstruation, and had become progressively worse until, at this time, it had reached the pernicious stage. The patient was much reduced and exhausted, but looked fairly well, and it was arranged that, should the remedies then suggested prove inadequate, interruption of the pregnancy must be undertaken without delay.

Three days later, I dilated and emptied the uterus, placing a strip of iodoform gauze in the cavity and packing the vagina lightly with the same material. The following day the patient became nervous and disturbed, and these symptoms continued during the greater part of her illness, the delirium at times becoming boisterous and agitated.

Three days after the curettage, she complained of pain in the left parotid gland, which was swollen and inflamed. Forty-eight hours later, a large quantity of thick yellow pus was discharged from the mouth. On the following day a fluctuating mass in front of the ear was opened under chloroform by the attending physician, and during the next twenty days four other abscesses or pockets, one of which was retropharyngeal, were incised and drained. On the fifth day after operation, headache developed. On the tenth day there was severe pain at the base of the skull, and on the nineteenth day there was a constant backward movement of the head, indicating a probable involvement of the meninges or encephalon. Muscular twitching and repeated up and down movements of the hands and feet occurred at intervals during the entire period of the disorder. Vomiting continued until the twelfth day following operation, when it ceased. No pelvic symptoms were noted until the nineteenth day, when urination began to give rise to great distress. On the twenty-first day the emptying of the bladder was, on one occasion, preceded by a slight convulsion. During the greater part of the time urine was passed freely, frequently involuntarily, but at

---

* Read before the Section on Obstetrics, Gynecology and Abdominal Surgery at the Sixty-Ninth Annual Session of the American Medical Association, Chicago, June, 1918.

times it became scanty and of a dark brown color, and deposited a large amount of sediment. There is no record that urinalysis had been made. Involuntary movement of the bowels was of frequent occurrence.

On the fourteenth day, a cough developed, sometimes accompanied by the raising of quantities of pus which the patient had evidently swallowed. On the eighteenth day, she complained of pain in the right lung, which was aggravated by coughing. During the whole course of the disease, free discharge of pus continued from the wounds and mouth, and later from the nose, and on the thirtieth day both eyes became filled with purulent material.

On account of the condition of the stomach during the early days of the sickness, the patient could retain no nourishment. Later the swelling of the neck glands and stiffening of the jaws prevented opening of the mouth, and forty-eight hours were sometimes passed without food of any kind. Nutrient enemas were begun early and tried repeatedly, but were generally expelled; at times the anus and rectum were so relaxed that the fluid escaped as soon as introduced. During the last day of life, tube feeding was resorted to. Saline by hypodermoclysis at times appeared to give temporary relief.

After thirty-three days of intense suffering, which toward the end was relieved only by hypodermics of morphin, the patient finally succumbed to the infection. During the entire illness the temperature went up only once as high as 103, generally fluctuating between normal and 101. The pulse was erratic, but never went above 140, usually running to about 100 or below.

This case was obviously one of profound septic infection. The source of the trouble is not, however, as readily determined. The case is unique of its kind; I find no other similar instance recorded.

RELATION OF PAROTID TO SYSTEMIC DISORDERS

In pagan times, when men ran up against a problem which they could not solve, it was carefully shouldered off as the work of demons. As late as the early nineteenth century, Christianity made the inexplicable a throwback on Providence, and later still the term "sympathetic" stood for the unknown, and "reflex phenomena" served as a cloak to ignorance of internal physiologic and pathologic processes.

The relationship between the parotid gland and systemic and local disorders has not, up to the present time, been satisfactorily elucidated. That symptomatic parotitis sometimes occurs as a grave complication in the course of infectious fevers has long been known, and that it is also an occasional sequela of other disorders, as amebiasis (Lesk), peripheral neuritis (Gowers), and the like, has been fairly demonstrated. In 1886 Paget directed particular attention to the fact that parotid bubo might develop as a rare secondary manifestation, following injuries to and operations on the abdominal and pelvic viscera, and he collected 101 cases from his own experience and the literature. In 1902 Morley added fifty-one cases to the list, and since that year a considerable number of instances have been reported in the medical press of this and other countries. Moreover, it has been found that symptomatic parotitis may follow other operations, though more rarely than those directed to the abdominal contents. Thus, MacDonald has seen cases of inflammation of the gland associated with railway amputations of the thigh, and Auld mentions an instance which followed trachelorrhaphy and the removal of hemorrhoids. Altogether there are now on record the reports and histories of several hundred cases of the condition, from which we may draw conclusions.

In specific parotitis, or mumps, the existence of a distinct connection between the disorder and the testes in the male and the pelvic organs and breasts in the female, especially during the child-bearing act, has been satisfactorily established, and Lavaran has shown that, in this form of the disease, the materies morbi is a specific organism, a small gram-negative diplococcus, which is presumably carried to the distant organ from the seat of the original focus. That the organism may be effective in its colonized environment in otherwise healthy males and females is sufficiently proved by many case reports. As long ago as 1855, in its obstetric connection, Homans mentions a case of mumps in a pregnant woman which extended to the uterus and led to premature delivery, and more recently similar cases have been recorded by Rook, Salter and others.

On the other hand, parotitis following septic (?) abortion and puerperal infection has received attention from a number of observers. Beuttner saw two cases of pyemia following abortion, in one of which metastasis to the parotid and the buttocks occurred; and in puerperal infection similar instances are recorded by Charriers, Davis and others. In both Davis' cases, abscess of the parotid complicated puerperal septicemia, from which both patients appeared very ill. Both patients also had pneumonia, and one died.

Now, if a path, as yet unrecognized, exists correlating the parotid gland with abdominal and other organs and parts, it is quite logical to assume that the arrangement is a two-way function, a premise which, admitted, at once makes clear why invasion of the gland by pathogenic organisms takes place after surgical procedures and in local pelvic infections.

The bacterial organisms found in most of the reported cases is the *Staphylococcus pyogenes-aureus.* In Davis' cases, which appeared to be of streptococcic nature, no bacteria were found in the blood or lochia, but the parotid pus contained staphylococci. Legueu and Morel have, on the other hand, found the *Staphylococcus aureus* in the blood associated with infection of the field of operation, and believe that this organism is the cause of the parotid disease.

According to Henning (quoted by Hoffstatter), the course of puerperal parotitis may run afebrile, but usually the temperature corresponds to the severity of the infection.

TWO SOURCES OF GLAND INVOLVEMENT

From an analysis of reported case of postsurgical and obstetric parotitis it is apparent that the etiology of the gland involvement must be sought in two sources: first in a general, and second in a local, infection. In the first, the process is embolic (metastatic), that is, it conveys the germs of toxins to the parotid gland from the involved organ or part.

One point in this connection, which is possibly of considerable importance, and which thus far seems to have been overlooked by most writers, is that the parotid alone of the three salivaries contains lymphatic glands. The slowing or stasis of the blood or lymph stream at these points would give rise to an accumulation of the causative agent in sufficient quantities to overcome the resistance of the gland and bring about the inflammatory sequel.

The second source of infection is through Stenson's duct. From a study of the involvement of the parotid gland in other conditions, it is evident that the oral cavity plays a more important rôle in the production of parotid bubo than is generally believed. The mouth contains a large and varied flora, which under ordinary circumstances is harmless; but some bacteria, after operations, may become virulent. The drying effect due to the anesthetic, and possibly due also to nervous influence in lessening secretion, the blood loss, the removal of water from the patient's body, due to limited intake of fluids and vomiting and possibly to mechanical insult, and the result of swabbing the mouth for the removal of mucus and vomitus all render the functionally disturbed gland increasingly susceptible to the invasion of the bacteria which, finding a suitable nidus in the abnormal tissues, at once develop a greater or less activity.

In the case I report, according to the nurse in charge, the mouth of the patient was foul from the beginning and the teeth were covered with sordes, before the emptying of the uterus was undertaken, and as the operation was conducted as aseptically as possible and no pelvic symptoms developed before the nineteenth day, when general infection was well established, I am of the opinion that involvement of the parotid gland in this instance was of oral, rather than of pelvic, origin.

32 Adams Avenue, West.

ABSTRACT OF DISCUSSION

Dr. E. E. Montgomery, Philadelphia: I have seen parotid infection follow various operative procedures and septic processes. In the great majority of cases, however, I was inclined to believe that the condition arose from transmission through the mouth rather than through the blood. The association of mumps with the development of orchitis and ovaritis has led to the belief that there is a very close relationship between these organs and the parotid gland, but all that can be said, I think, is that they were possibly more susceptible to the organisms which produced the glandular inflammation than other structures of the body.

Dr. M. E. Klingler, Garrett, Ind.: I recall a case of lobar pneumonia in the right lung in which the patient, 32 years of age, aborted an early pregnency on the fourth day. This was followed on the next day by left-sided parotitis without formation of pus. On about the twentieth day there was a right-sided hepatitis, also without pus. Finally, on the thirty-fifth day an appendiceal abscess developed, which was opened and drained and the appendix removed. Subsequently there was a left-sided empyema on about the fiftieth day, followed by complete recovery.

Dr. Stephen E. Tracy, Philadelphia: I have seen two or three cases of parotitis follow operation, but they all cleared up promptly. I am inclined to believe with Dr. Montgomery that in some of these cases the infection originates in the mouth. For that reason more attention should be paid to the condition of the mouths of our patients than has been done in the past. The profession is beginning to give this subject more consideration. It is well to bear in mind that a patient with soreness at the angle of the jaw may have a more serious condition than an infection of the parotid gland. A year and a half ago I operated on a patient who eight or ten days later complained of soreness at the angle of the jaw. I thought at the time that she was developing a parotitis. In thirty-six hours it was evident she had tetanus. It is well to keep this in mind, as such a condition requires prompt and energetic treatment.

Dr. W. P. Manton, Detroit: The condition which I reported following the emptying of the uterus is rare; at least, I have been unable to find any record of such a case in literature. Even up to the present time surgeons are claiming that these cases of infection of the parotid are sympathetic. I am not a believer in "sympathy" of that kind. That the infection may take place through the mouth is a well settled fact.

CLINICAL SUPERVISION OF THE WELL BABY DURING THE FIRST YEAR*

H. H. YERINGTON, M.D.
SAN FRANCISCO

With the enormous amount of work going on in Europe at this time, the need of more organized work in the conservation of child life is beginning to be felt in this country. This work has its foundation, for the most part, in our large public clinics, and the ones doing the greatest work are those having the proper organization for handling it.

Those of us who have spent many years in clinic and hospital work and are connected with teaching institutions have often felt that constructive work in the ordinary clinic is lacking, that great numbers of our patients go home with improper treatment and that the work on the part of the clinicians becomes monotonous.

It has seemed to me that the factors in making a children's clinic a success are the following: (1) a supervising head who is present at all times during clinic hours, capable of attending to the executive work, and directing the teaching; (2) individual care of the various patients by the same clinician; (3) the division of the clinic into different parts, each part headed by a clinician interested in a certain line of work, and a specialist in it; (4) the proper teaching of students, nurses and also mothers; (5) a close connection between the prenatal clinic and children's and obstetric services in the hospital; (6) the social service worker, who is indispensable in such an organization; also the convalescent home, which should be a part of the clinic.

DEVELOPMENT OF SPECIAL CLINICS

The plan of special clinics in the children's department of the Stanford University Medical School was developed several years ago under the direction of Dr. Langley Porter, the first being a special clinic in congenital syphilis starting in 1911. Since then the following have been established, each under a separate head: mental deficiency, prenatal, adolescence, children's chest clinic, well baby clinic, whooping cough, and a special division in the baby clinic for the instruction of mothers and students in dietetics.

The big advantage in developing clinics is that the patient gets much better care, the work of the student is more concentrated, and the clinician takes pride in developing his own side of the work and obtains valuable material for scientific research. As this paper deals with the supervision of the well baby during the first year, I shall consider only that part of the organization dealing with this subject.

In 1907 the mortality of the infants up to 2 years old in the San Francisco Foundling Home was 59.7 per cent. The next year the Associated Charities put their foundling babies in private homes, the food was ordinary commercial milk, and there was no special supervision. The mortality dropped to 12.5 per cent. These figures would seem to settle the case for the foster home. In 1909 the baby hygiene committee of the Collegiate Alumnae began to cooperate with the

* Read before the Section on Diseases of Children at the Sixty-Ninth Annual Session of the American Medical Association, Chicago, June, 1918.

Associated Charities. They made possible the use of certified milk and physicians rendered clinical and medical care.

From 1909, the mortality of the boarded-out infants continued to drop until in 1916 it was 2.67 per cent. in contrast with 8.7 per cent., the average death rate of babies of the same age in the city of San Francisco.

THE CLINIC AT WORK

The present system of the Associated Charities' work operates as follows: First, a home is carefully selected and the baby is placed in it. Second, the social worker and nurse watch the home and baby, certified milk is supplied, and the mother is taught how to modify the milk. Third, the baby is brought to the clinic every Friday and its feeding and care supervised by Drs. Holsclaw and Rude who deserve the credit for the remarkable work done by this organization. During 1917, 245 babies were cared for, of whom nine have died, the mortality being 3.67 per cent.

The problem of caring for infants in a general clinic is somewhat different and more complicated. The principal difficulty is in the fact that it is much harder to get the mother to cooperate than the foster mother, and the supervision over the babies is not as close. Feeling, therefore, that there was a big field in the education and care of the mother and child coming to our general clinic, we decided to establish a well baby clinic one day a week for these cases. Such a clinic was established a year ago last September and has been growing rapidly since.

In order to do any constructive work in a clinic of this nature a close association of the prenatal and adolescent work is indispensable. The adolescent clinic has been established two years, and is on a firm foundation, and a survey of its first hundred cases was made and published recently by Dr. Amelia Gates.[1] A movement has been started to teach adolescent girls infant hygiene and formula making by combining the two clinics together one day a week.

This year the prenatal clinic under the department of gynecology and obstetrics had a total of 942 visits, many of the mothers having already had the educational advantages of the baby clinic.

PROGRAM OF THE WELL BABY CLINIC

The plan adopted in the well baby clinic is as follows: The clinic is held every Friday morning in separate rooms fitted up for this purpose, with a reception room, weighing and examining room, and a large outer room with three desks for the clinicians. The histories are brought from the central history room, the baby is undressed and weighed and the weight reported by a volunteer worker. The social service worker supervises this work, discussing home conditions and needs of the parent, and the histories of the babies are then brought into the outer room to be observed by the physician.

The babies are brought for examination every week for the first three months, every two weeks from the third to the sixth month, and every month from six months to one year. They are transferred then to the general children's clinic. Every mother delivered in either the maternity ward in the hospital or in the outpatient obstetric service is given a card asking her to report with her child to the baby clinic when it is 3 weeks old. From May, 1917, to May, 1918, there were 2,146 visits to this clinic, 348 being new cases. Of 290 deliveries in the hospital 194, or 67.8 per cent., returned to the baby clinic. Of 126 deliveries on the outside service, fifty-three, or 42 per cent., returned. This shows a close bond between the hospital cases and the baby clinic.

In order to stimulate the work and keep a check on such a clinic, the social service worker, of course, plays the leading rôle. A card system is kept, postals are sent to those not attending the clinic, and if there are no responses the cases are followed up in the homes. At the present time, more than 200 calls a month are made by the social service workers connected with the children's clinic. In the organization of a clinic of this kind, intimate knowledge of the home surroundings of the infant is of great importance, and the sympathetic relationship between the social service nurse and the mother is imperative.

A STUDY IN INFANTS' WEIGHTS

It is somewhat early to tabulate data obtained in this clinic, but some of the following points may be of interest. Last year Faber and Murry began a study of weights of San Francisco infants. They took the weights of babies born in the maternity and outpatient obstetric services of Lane Hospital, and the babies coming into the clinic. If any child came for malnutrition or any chronic disease, his weight was discarded as abnormal, and twins and premature infants were excluded. There were 2,966 weights taken from 246 boys and 275 girls and thirty-four from infants whose sex was not recorded. The average weight at birth in this series was: males, 3,500 gm., and females, 3,311.7 gm., or an average of 3,432 gm. Holt gives an average of 3,345 gm., which is 87.3 gm. less than the foregoing.

They summarize the results as follows: The initial loss in weight is greater in San Francisco babies' averages by about 38 gm., and the return to the original weight occurs approximately the same time, that is, in ten days. At the end of the first month, the San Francisco babies are heavier than those recorded by Newman and Holt, but not as heavy by 77 gm. as those observed by Robertson of England.

By the end of the first year, however, this loss is made up and the San Francisco infant's weight is 329 gm. heavier than that of the baby of any other locality previously recorded. This gain over other infants is no doubt due to the evenness of the climate and the lack of any season unfavorable for growth. The breast-fed babies show this regularity in development particularly well. The maximum growth occurs in August and the two and three months following, and this agrees fairly well with the most careful similar records made by Bleyer.

INSTRUCTION IN INFANT FEEDING

In our method of feeding we have endeavored to instruct the mother to nurse her baby as long as possible, later adding bottle feedings, beginning with one a day when the child's weight becomes stationary or the mother's condition warrants it. Examination of the breast milk we have found of little value as compared to the clinical manifestation of a diminished milk supply. I have felt that formulas of the simplest kind should be used in such a clinic, both as a ground work for students and because of the simplicity in making up the formulas. Dilutions of certified milk and water are used first and barley water substituted for water at the beginning of the third or fourth month. Cane sugar and one of the maltose and dextrin products have been the carbohydrate of choice, it being found that this combination regulates the bowels and is well handled by the great majority of our infants. At the age of 6 or 7 months, the feedings are changed from a three to a four hour interval, and fruit juices, cereals and broths are added, and at the age of 1 year a generous diet is given. The class in this course is limited to four students and covers a period of three months. They follow their own cases under the eye of an instructor, and with an average of fifty cases a morning, the instruction is very intensive. Both the caloric and the percentage methods are used in this work.

THE CONVALESCENT HOME

Last year the people of Palo Alto who are interested in the university subscribed a sum of $2,000 for the establishment of a convalescent home for the clinic children. It was open for three months during the summer and ninety children were cared for. This year a similar sum will be subscribed and we plan to accommodate about forty children a month for a period of three months. We cannot care for the infant of less than 1 year old as yet, but the home will be there for any building up the baby needs during the run-about period.

When I left San Francisco, the program of Children's Year had been launched, and the first week's work had proved more successful than any of us anticipated. In view of the fact that the Associated Charities, the University of California, and Leland Stanford Junior University all have well established baby clinics and that others are being organized, I feel that we in the Far West are laying the foundation for a big work in the reduction of infant mortality.

ABSTRACT OF DISCUSSION

Dr. C. F. Wahrer, Fort Madison, Iowa: In the past it would have seemed foolish, if not silly, to have a clinic for the well, but what seems foolish in one age becomes the rule of life for another. A long time ago it was suggested that when a woman was expected to be confined, she should put herself in touch with her family physician and report any abnormalities. When I began practice thirty-five years ago it was the rarest occurrence for a woman to want me to confine her until she was in the second stage of labor. Sometimes I would be called on a case, and I had not the faintest idea until I arrived there whether it was a broken leg or a baby. Luckily for the poor patient, this state of affairs is passing, except in the most remote districts. In most cases now we are able to get the patient to report some time before, with much better results for mother and babe. Whenever a babe is born we have in the near future a potential patient, and the physician who attends the mother during the birth of the child, especially in the outlying districts away from the medical centers, should have the constant care of that child. The mother should be taught to be on the watch for symptoms of approaching trouble and keep the physician informed, and in this way many serious results would be avoided. This is easy now, as the physician is usually in telephone connection with all his patients.

Dr. Louis H. Schwartz, New York: I have conducted a "well baby" clinic for about twelve years. During that time we have taken care of about 11,000 babies. We have active social histories of about 10,000 babies. I was much interested in Dr. Yerington's description of his clinic. Our prenatal work has been well organized only recently. We have tried to get our babies as soon as possible after birth. With better organization we will get them much earlier than we do. These 10,000 family histories have been gotten in ten years by the same social worker, who speaks four or five languages. These babies represented 5,000 families—20,000 pregnancies of all sorts—stillbirths, miscarriages, full-time births, etc. Eight per cent. were miscarriages; about 1.5 per cent. were stillbirths; infantile deaths were about 12 per cent. Children up to 8 years of age were counted. That is to say, of the 20,000 pregnancies, 5,000 were useless up to the age of 8 years—in other words, a 25 per cent. loss of life. If we view that as compared with the lower animals, I wonder how much preventable death that represents. Put it in another way: The miscarriage rate in these families was 80 per thousand; stillbirths, 10 per thousand. The infant death rate as compared with the viable pregnancies, so to speak, is 131. Child death rate up to 8 years, per thousand pregnancies of all kinds, is 161, and child death rate up to 8 years as compared with a thousand viable pregnancies, is 178. That is to say, 178 of every thousand viable children die before the age of 8 years. For our children we might say we have a death rate of 64 at this clinic instead of 126 that the entire family has. The same class of patients before they came to our clinic had a general death rate of 126 per thousand. Under our care, in the same city, in the same surroundings, they have now a death rate of only 64 per thousand.

THE PRINCIPLES OF TREATMENT IN MERCURIC CHLORID POISONING

WITH RESULTS OF TREATMENT *

H. B. WEISS, M.D.
Lieutenant, M. R. C., U. S. Army; Instructor in Medicine, University of Cincinnati College of Medicine; Assistant Attending Physician, Cincinnati General Hospital
CINCINNATI

Within the past two years there has been much work done in the various phases of mercuric chlorid poisoning. Before then, most of the work reported was of a therapeutic nature; but recently, new and important laboratory data have been contributed. These new data have certainly put the modern therapeutic measures to the test, discrediting many and placing a few on a firm basis.

The anatomic pathology has been well established. Every organ of the body is affected, the liver and kidneys bearing the brunt of the injuries. From a cloudy swelling the changes continue to fatty degeneration and necrosis. When the poisoning is severe, hemorrhagic inflammation may supervene.

Schamberg, Kolmer and Raiziss,[1] in their studies of the comparative toxicity of the various preparations of mercury used for therapeutic purposes, have shown in a long series of dogs that every animal develops evidences of nephritis of varying degrees after injections of both the soluble and insoluble mercury salts. The nephritis produced is primarily tubular, with frequent accompanying glomerulonephritis (hemorrhagic) in the severer instances. The changes in the tubular epithelium they attribute to a direct toxic degeneration of the cells by the mercury, and not to an inflammatory reaction depending on the elimination of toxic substances.

Mercury has been obtained from the blood of dogs within ten minutes after its administration by mouth.[2] Burmeister and McNally have shown that the kidney

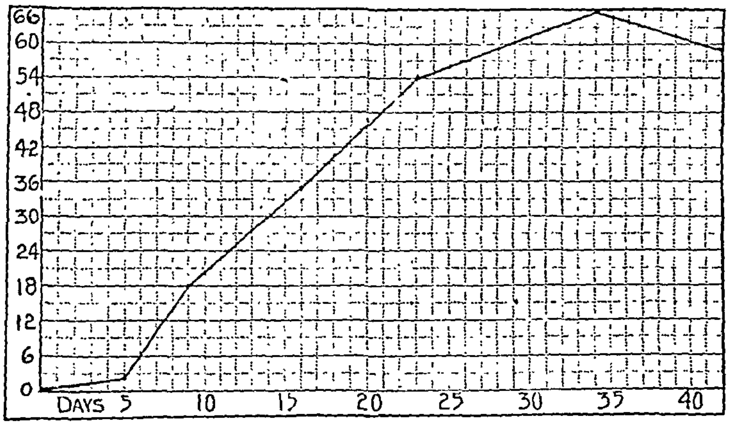
changes vary with the size of the dose in massive intoxication, and that the liver changes depend on the duration of the intoxication.

The important newer studies consider the question from a chemical standpoint. It is from this point of view that the present treatment must be evolved.

As the mercury is quickly taken up by the blood after ingestion, it is evident that all the tissues are quickly bathed with the toxic material. In a fatal case of mercury poisoning, it was found that almost one third of the mercury recoverable from the body was obtained from the blood.[3] In 1916, Lewis and Rivers[4] found that the retention of waste nitrogen was a factor in the production of early fatalities. More recently MacNider,[5] in an exhaustive study, has demonstrated some essential facts. Those animals that did not succumb from the early gastro-enteritis developed a severe type of acid intoxication, as evidenced by the production of acetone bodies, the reduction of the alkali reserve of the blood, and the increase in carbon dioxid content. Constantly associated with this acid intoxication was a kidney injury. He states that delayed kidney injury is not due to the action of the mercury as such during its elimination by this organ. He[6] had previously shown that acetone and diacetic acid are developed in nephritis produced by uranium, and that administration of alkaline carbonates lessened the toxicity of the uranium and delayed the formation of the acid bodies. Furthermore, when the kidney was protected by carbonate, it was found that the kidney remained functionally more active, and that there was a diminished acute swelling, fatty degeneration and necrosis of the renal epithelium.



Percentage of phenolsulphonephthalein output after a patient who developed anuria for three days began to void.

It is this work which has proved correct the therapeutic principles that I have employed in the treatment of mercuric chlorid poisoning.[7]

The symptoms of poisoning by mercury are well known: locally burns, and later vomiting and gastro-intestinal hemorrhages; as the toxemia progresses, oliguria, then anuria and finally "uremic" symptoms, as convulsions and death.

Many remedies, empiric and allegedly scientific, have been advocated in the use of mercury poisoning, but they seem not to have stood the test of time. We have used the alkaline treatment for more than three years, and our records show a lower mortality than that ordinarily reported.

The principle involved in the use of alkali is that of trying to counteract the acid intoxication produced, which *in turn produces the* generalized toxemic swelling and degeneration of all the body tissues.[8] When there is present oliguria, with blood and casts in the urine, we have evidences of acute kidney injury. This discernible kidney injury is merely an indication of an injury common to all the body tissues, for we know that the entire organism has been bathed by the mercury. The alkali is not given as an eliminant, but to counteract acid intoxication, edema and cloudy swelling, which, if permitted to go on, proceed to fatty degeneration and irreversible cell damage (necrosis).

Sansum,[9] in a recent paper, seems to believe that the basis for the use of alkali is to be found in its power to increase diuresis with a secondary washing out (increased elimination) of mercury. Because he finds no increased mercury elimination, he leads his readers to suppose that the use of alkali as a therapeutic agent is valueless. The alkali, however, is not used solely for its eliminatory action, but to inhibit and to counteract damage to the tissues which mercury, if left to itself, produces.

At present we can report on fifty-four consecutive cases of mercurial poisoning with but three deaths. Of the three patients that died, two received the treatment only after unavoidable delay, and one had a preexisting nephritis and cirrhosis.

METHOD OF TREATMENT

Essentially the treatment which I have proposed consists of an early washing out of the mercury salt from the stomach and intestine and continued introduction of sufficient alkali to overcome the acid intoxication.

The patient should come under observation as early as possible, for I have found that when the treatment is delayed for any reason, the symptoms produced by the mercury posioning become more difficult to control. Two patients of my series died, I think, because treatment was commenced too late.

I usually wash out the stomach with a mixture of 1 quart of milk and the whites of three eggs, following this by a saturated solution of sodium bicarbonate until the stomach washings return clear. Finally, before the stomach tube is removed, from 3 to 4 ounces of crystallized magnesium sulphate dissolved in from 6 to 8 ounces of water are allowed to remain in the stomach. A soap suds enema is then given.

Usually the patient vomits shortly after taking the mercury, thereby aiding in the elimination of the poison.

The next step is to introduce alkali, and we give the alkali by mouth, rectum and intravenously. As soon as possible after washing the stomach, the patient is given Fischer's solution intravenously. Fischer's solution consists of crystallized sodium carbonate, 10

gm. ($Na_2CO_3.10H_2O$), (or 4.2 gm. of the ordinary "dry" salt); sodium chlorid, 15 gm., and distilled water, 1,000 c.c.

Depending on the state of the circulatory system, from 1,000 to 2,000 c.c. of the solution are given intravenously as a first dose. We continue the alkaline medication by giving 8 ounces of "imperial drink" every two hours. This drink consists of: potassium bitartrate (cream of tartar), 4 gm. (1 teaspoonful); sodium citrate, 2 gm. (½ teaspoonful); sugar, 2 gm. (½ teaspoonful), and water, 240 c.c. (8 ounces).

This drink is flavored with lemon or orange juice. The patient is allowed large quantities of it.

There is no restriction in diet at any time during the treatment.

As an indication of the severity of the acid intoxication, and as a guide to the amount of alkali and salt that needs to be given, we use the analysis of the urine. Except in suppression cases (which were rare in our series), the patient voids large quantities of urine, the amounts depending on the amount of fluid taken. The urine should become alkaline to methyl red (a saturated solution of methyl red in alcohol) and be kept so, for Fischer has demonstrated that if the urine of a nephritic cannot be maintained alkaline to methyl red, the patient continues in a serious state. If the output of urine is not seen to be maintained, and if its reaction does not become alkaline to methyl red after the first intravenous injection, a second intravenous injection is given the following day, and general alkali administration by mouth or rectum is continued.

RESULTS

Under this treatment, there is usually produced and maintained a free secretion of urine which *remains* alkaline; and an output of albumin in the urine, which usually develops early, rapidly disappears. Ordinarily, two intravenous injections of the alkali, together with the solution of potassium bitartrate and sodium citrate, which is given at hourly or two hourly intervals day and night (when the patient is not asleep) has been found sufficient to keep the urine alkaline and to keep the output of urine normal. The blood and casts in the urine are usually quickly dissipated. The patient is kept under observation for about ten days after the urine has become normal, and is then discharged.

I have shown previously[10] that patients treated early show fewer symptoms and make a more rapid recovery than those in whom treatment is delayed.

We have performed phenolsulphonephthalein tests on most of our patients, and it is interesting to note that those who were treated early showed only slight or no diminution in phenolsulphonephthalein output. When the output was diminished, it rapidly rose to normal and continued so. In one patient who developed an anuria for three days,[10] the phenolsulphonephthalein output was practically zero for five days after he commenced to void, and then rapidly rose to 66 per cent. (as shown in the accompanying chart) at the end of thirty-three days. This patient's urine was normal six months after his recovery from the mercuric chlorid poisoning.

Value of Authorities.—Authority is useful as a factor in critical judgment; it is fatal as an object of worship.—E. P. Lyon.

THE PULSE AFTER A MARATHON RACE

PAUL D. WHITE, M.D. (Boston)
FRANCE

The question of the possibility of producing alternation of the pulse by very vigorous and prolonged exertion was the incentive to a study of the pulse of twenty men who ran the annual Boston Marathon of 25 miles from Ashland to Boston, April 19, 1916.

Myocardial exhaustion resulting from damage such as that produced by arteriosclerosis or syphilis has been shown to be an important cause of alternation of the pulse. The greater the strain on such a heart, the more marked is likely to be the alternation. The strain necessary to sustain a high blood pressure is especially likely to bring out alternation. Extreme and prolonged tachycardia, as in auricular flutter or paroxysmal tachycardia, may result in pulsus alternans. But it has never been shown, so far as I am aware, that alternation has been found in the pulse of a normal individual after severe exertion. Von Tabora[1] stated that he had been unable to detect pulsus alternans in cyclists who had covered the distance from Leipzig to Strassburg, a distance of 260 miles as the crow flies; no note was made as to the speed of the cyclists.

The Marathon run is probably as severe a physical effort as has ever been undertaken in athletic contests, and many of the men who finish are in a state of collapse after the race. It was from twenty contestants that radial pulse tracings were taken with the Mackenzie ink polygraph within five minutes of the time they completed the race. Tracings covering two or three minutes' time were taken in each case. Three polygraphs were used. The men investigated were all young and healthy. Their positions at the finish were: 3, 4, 6, 7, 8, 10, 13, 14, 16, 17, 18, 19, 20, 21, 22, 23, 25, 27, 29 and 32. Thirteen of them finished the 25 miles within three hours, and the third man in ran the race in two hours, twenty-eight minutes and thirty seconds.

No alternation of the pulse was found in any tracing. Marked sinus arrhythmia was found in two cases, but the only abnormal arrhythmia was one ventricular premature contraction found in the third man to finish. This premature contraction was not followed by alternation. The pulse rates as calculated from the tracings ranged from 72 to 107, with an average of 91. In general, the pulse is smaller after the race than before.

In 1915, the pulse of six of the runners was felt before and immediately after the race. The rates were: 64 before and 136 after, 86 and 120, 60 and 140, 62 and 108, 80 and 80, 118 and 110. The last man noted was the winner; he was obviously very nervous before the race, as he had good hopes of winning. These pulse rates were taken with the men standing, while the tracings were taken in 1916 with the men lying flat. The rapid vagal action probably accounts for the generally slower rates found in the latter group. No irregularity was felt in 1915. In the case of one runner who collapsed on the course and who was brought in by automobile to the finish, a thready pulse of 80 was counted. He seemed to be in a condition of shock.

---

[1] Von Tabora, verbal communication to Gravier, L.: L'Alternance du cœur, Paris, 1914, footnote, p. 278.

Electrocardiograms taken in 1915 of the winner, Fabre, and of a runner who finished late in the list, showed nothing abnormal except possibly very slight prolongation of conduction time. They were taken two hours after the finish of the race. The winner had at the start of the race the highest pulse rate counted, 118. It was 110 when he finished.

SUMMARY

Marathon racing does not exhaust the healthy heart sufficiently to produce alternation of the pulse.

A FILTRABLE TOXIC PRODUCT OF THE HEMOLYTIC STREPTOCOCCUS *

ADMONT H. CLARK, M.D.
First Lieutenant, M. R. C., U. S. Army
AND
LLOYD D. FELTON, M.D.
Contract Surgeon, U. S. Army
BALTIMORE

The following is a brief statement of the methods and results of experiments in which a filtrable substance toxic for rabbits has been obtained from cultures of hemolytic streptococci isolated in cases of bronchopneumonia occurring in Army camps. Though various workers at different times have obtained toxic materials from streptococci, yet we have so far been unable to find any report of methods or results directly analogous to these. The observations that led to the work were made simultaneously and independently by each of us.

The essential feature of the method was the cultivation of the streptococcus in a medium consisting of sterile, defibrinated rabbit's blood diluted with Locke's solution. The Berkefeld filtrates from such cultures were acutely toxic for rabbits, while uninoculated hemolyzed controls incubated for the same time were nontoxic. Toxicity in the culture medium did not appreciably appear before eighteen hours, reached its maximum at about forty-eight hours, and was still evident at ninety-eight hours. No definite relation between oxygen tension or anaerobiosis and toxicity of culture filtrates could be determined. Until the present time the greatest toxicity has been obtained from a blood-Locke's mixture that gave a reading of about 20 per cent. hemoglobin with a Sahli hemoglobinometer. A Locke's solution containing 0.15 per cent. of glucose has seemed most effective for dilution. This mixture when inoculated and incubated at 37 C. for forty-eight hours has yielded a sterile filtrate, 0.5 c.c. per kilogram of which killed three out of twelve rabbits injected simultaneously, while 1 c.c. per kilogram killed five out of six. This illustrates the fact that within certain limits there was a distinct individual variation in the susceptibility of different rabbits to a constant dosage. Six different strains of streptococci were grown in this medium, and all yielded toxic culture filtrates. When injected into rabbits, an incubation period varying generally from four to twenty-four hours elapsed before the symptoms appeared, the time depending to a considerable extent on the dosage. These symptoms were a slowly increasing weakness, accompanied often but not invariably by diarrhea, with death finally occurring with or without convulsions. Intravenous, subcutaneous or intraperitoneal injection gave death in about the same period of time. As controls, other nonrelated organisms were grown in the medium. Single strains of *Bacillus coli*, *B. lactis-aerogenes*, a gram-negative organism obtained from the air, and a hemolytic *Micrococcus catarrhalis* grew abundantly and produced hemolysis in the medium; but after filtration when injected into rabbits, no toxicity was demonstrated. This indicated that the toxicity that appeared in streptococcus cultures was not dependent alone on hemolysis.

While the medium described above is efficient in yielding a toxic filtrate, numerous experiments were carried out to determine some factor which, in the presence of the growing organisms, was necessary for the production of this toxic effect. Various modifications of meat infusion broth were invariably negative with the strains of organisms used. Rabbit's liver, spleen, kidney and heart muscle when washed free from blood and chopped and mixed with Locke's solution, while allowing a luxuriant growth of the organisms, gave nontoxic filtrates.

Rabbit blood serum did not yield any toxicity. If, however, the washed corpuscles from this blood were mixed with a volume of Locke's solution equal to that of the serum removed and the streptococcus grown in this medium for forty-eight hours, the resulting filtrate showed the full toxicity. The toxic product of the streptococcus growing in a medium of blood seemed, therefore, to be derived from some factor in the red blood cells. An attempt was made to separate the various constituents of the red blood cells to determine, if possible, which factor was the source of the toxic substance. Blood cells were washed with Locke's solution, and the stroma obtained in a pure, colorless condition according to the method of Woodbridge. No toxicity could be obtained from a medium consisting of Locke's solution and this purified stroma. A cholesterinized broth medium was negative. The filtrate from a culture in a colorless medium made by the precipitation of the blood pigments with chloroform from washed corpuscles, containing about 12 gm. of protein per liter, was nontoxic. Globulin obtained from washed corpuscles by the method of Morend was dissolved in alkaline Locke's solution and then neutralized. Growth of the organisms was excellent, yet large doses of the filtrate were nontoxic. The chemical preparation of these fractions obviously alters their native condition, yet the negative findings are of interest. These experiments, therefore, suggest at least that the toxic effect of the streptococcus growing in the rabbit's blood medium is due to a substance or substances elaborated in the interaction between the growing organisms and the hemoglobin fraction of the red blood cells.

Certain characteristics of this toxic substance were determined. It did not produce any hemolysis in vivo or in vitro, though the growth of the organisms in the medium itself caused extensive hemolysis. The toxic material was definitely dialysable through collodion membranes of the proper degree of permeability. While the dialysates were seldom as pigmented as the original medium, no toxic dialysates were obtained that were entirely colorless. Complete thermal inactivation occurred at 50 C. in thirty minutes without a demonstrable change in the physical properties. Heating to 45 C. for the same length of time gave no alteration in toxicity. Toxic culture filtrates showed a marked diminution in toxicity after standing a few days in the ice box. Exposure of a rabbit to sunlight did not increase the effect of a toxic injection.

---

*From the Pathological Laboratory of the Johns Hopkins University.

Immunologic tests, as far as they have been conducted, yielded the following results: Toxic filtrates were injected into rabbits in increasing amounts. Immunity was acquired against multiple lethal doses. It was found possible, occasionally, by beginning with small inoculations, to double the dose at successive daily intervals without any noticeable reaction aside from variations in weight. Until the present time no attempt has been made to increase the immunity beyond six lethal doses; but the ease with which this degree of resistance was acquired would indicate that a much higher degree could be established. This immunity, at the end of about a month since the last injection, did not seem to be diminished. An immunity against the toxic product of one organism also gave an immunity against that of another. Blood from an immune rabbit conferred a certain degree of passive immunity on normal rabbits injected with lethal doses of toxic material. For example, a normal rabbit given 1 c.c. per kilogram of toxic filtrate intravenously died in thirty hours. Five other normal rabbits were given 2 c.c. per kilogram of the same toxic filtrate mixed with 0.1, 0.25, 0.5, 1 and 2 c.c. of defibrinated immune blood. Aside from a temporary slight weakness in those with the smallest amount of blood, no effect was evident. Immune serum also confers this passive immunity. Normal blood and serum did not have a comparable degree of protective power.

A series of rabbits immunized against toxic filtrates was given varying quantities of living virulent streptococci. Not only were they resistant against minimal lethal doses of the organisms, but in several of the animals large intravenous injections of the living cultures were tolerated. As much as 20 c.c. per kilogram of a culture gave no symptoms in a rabbit which more than a month previously had received the last injection of three lethal doses of a toxic filtrate. A normal control died in forty-eight hours with 1 c.c. per kilogram of the same culture. It was quite evident in this series, therefore, that immunity against the toxic product of the organisms gave an immunity against the organisms themselves, and that an active immunity persisted for at least a month. This immunity was also effective against strains of the hemolytic streptococcus other than that which was used as antigen.

The question as to whether immune serum will or will not confer a passive immunity against living organisms has not as yet been definitely determined.

The relation between the toxic filtrates and the virulence of the organisms is illustrated by one experiment in which one fifth of the lethal dose of toxic filtrate increased the rabbit's susceptibility to such an extent that one fortieth of the lethal dose of living culture caused death.

A few experiments have been carried out in which the pneumococcus and staphylococcus have been cultivated in the rabbit blood-Locke's medium in the same way and have been found to yield filtrates that were toxic for rabbits.

SUMMARY

It has been found that hemolytic streptococci grown in rabbit's blood diluted with Locke's solution yield a filtrate that is toxic for rabbits occasionally in doses as low as 0.5 c.c. per kilogram. The formation of this toxic material is dependent on the presence of hemoglobin. It is destroyed by heating to 50 C. for thirty minutes; it is dialysable; it requires a certain incubation period in the animal before exerting its toxic effects; it is nonhemolytic in vivo or in vitro; it slowly loses its toxicity on standing at ice box temperature; an immunity can be rapidly established against it, and the blood of immune rabbits when injected with the toxin has the power of neutralizing its toxic effects; rabbits immune against the toxic substance are resistant to living streptococci.

THE TREATMENT OF AMEBIC DYSENTERY WITH IPECAC BY RECTUM

GEORGE B. LAWSON, M.D.
Physician to the Jefferson Hospital
ROANOKE, VA.

Brem and Zeiler,[1] in 1911, successfully used ipecac by rectum and through the appendix after appendicostomy in several cases of amebic dysentery that had not yielded to other methods of treatment. This method does not seem to have come into any general use. We have been using a similar method for about five years, although, up until recently, we were ignorant of Brem and Zeiler's work. Our number of cases has been somewhat limited, and it is only in the past year that we have been able to test this method to our satisfaction. Our method of procedure is to put 60 or even 120 grains of powdered ipecac into about 24 ounces of water; this is kept hot for an hour, but not allowed to boil. After washing out the bowel with warm water, this whole preparation, without filtering, is given slowly by rectum to be retained as long as possible. If there is much pain and tenesmus, only a part of this can be given. In a few of our cases, there was some discomfort and the treatment had to be slowed down. Formerly, we used this method of treatment, and, at the same time, gave the salol-coated ipecac pills. Later on emetin (alkaloid) came into use; we used this hypodermically and gave the ipecac by rectum. In two cases—which we are reporting—the ipecac was used by rectum without other treatment:

Case 1.—J. T. M., white man, aged 63, presented himself for examination, Dec. 4, 1917, complaining that the rectum felt as if it would pull out, and of having from five to six stools a day. The general history was negative except for a severe typhoid at the age of 31. The present illness began five years before, while the patient was selling groceries in Roanoke, Va. He gradually commenced to have a diarrhea, which has been better at times and worse at others. In 1915 he was kept in bed one month and treated with quinin enemas. In the spring of 1916 he was given emetin hypodermically in rather large amounts, with salol-coated ipecac pills by mouth, and was also given chaparro amargosa without much improvement. In February, 1917, he was given arsphenamin intravenously with improvement for nearly four months, with relapse at the end of this time. Later on, he was given another treatment of arsphenamin without any improvement. Since then he had fared badly, as a rule; the bowel was always full of gas and there were from two to six movements a day, with some blood-tinged mucus. The man was undernourished, but in fairly good shape as a whole. Rectal examination revealed a large number of superficial yellow ulcers; the mucus from the rectum showed much pus, red blood cells and many large active motile amebas containing red blood cells. The Wassermann test was negative. The patient was given the ipecac preparation by rectum every day, with immediate betterment of symptoms. The amebas, pus and blood soon disappeared from the stools, and for five and a half months he has had no trouble whatever. He has been using an occasional ipecac treatment during this time. At no time during this treatment has he been dieted in any way, or has he stopped his regular work.

---

[1] Brem, W. V., and Zeiler, A. H.: Medical Treatment of Amebic Dysentery, New Orleans Med. and Surg. Jour., July, 1911.

Case 2.—H. E. D., man, developed amebic dysentery while a soldier in the Philippine Islands during the Spanish-American War. It took him a long time there to get well. He remained in good shape until about five years ago, when the dysentery increased, and, on presentation for examination, he showed very many motile amebas containing red blood cells; he also showed a heavy trichomonas infection. We began immediately to use the ipecac by rectum. The symptoms disappeared almost at once, and the amebas disappeared almost immediately from the stools.

We believe that the hypodermic emetin treatment for dysentery can be greatly aided by also giving ipecac by rectum. It certainly seems preferable to apply a treatment locally rather than have it traverse the whole alimentary canal before reaching the seat of the disease. It also seems better to use the ipecac, or some form of ipecac, by rectum rather than give it hypodermically where it will diffuse through all the tissues of the body by the time it reaches the seat of the disease. Since the barium enemas can be seen with the fluoroscope to pass up to the cecum, we believe this ipecac preparation very rapidly spreads to all the surface of the large bowel, where it can have a direct local effect and the soluble portion can be absorbed even into the deeper tissues. The administration of ipecac by rectum has the advantage that it can be used by the patient when away from his physician.

Clinical Notes, Suggestions, and New Instruments

A NEW CONTACT TEST FOR ALBUMIN IN URINE*

Ulmont P. Stewart (New York)
Second Lieutenant, S. C., U. S. Army
Camp Gordon, Atlanta, Ga.

Certain observations, made over a period of years, convinced me that a rapid and reliable contact method for the detection of albumin in urine was desirable. The method described is the outcome of nearly three years' work with various reagents.

Because of its general use and reliability, the heat test has been taken as a standard. A number of reagents, such as Tanret's solution, were tried out and found to be entirely too sensitive. Positive reactions were obtained with mucin and proteose in urines which were otherwise normal. Still other reagents, such as concentrated nitric acid, were found to be less sensitive than the heat test, negative reactions being frequently obtained with pathologic specimens.

The heat test, although very reliable, is too time consuming when a large number of specimens are to be examined. The use of acid in dissolving phosphate precipitates may also carry the albumin into solution, if only a faint trace is present. The agitation necessary to dissolve the precipitate completely may so diffuse the albumin that the reading is doubtful. The method described is very rapid and duplicates closely results obtained by the heat test. The technic of applying the test has been in use for a number of years, being formerly used for the nitric acid contact test.

This solution being too concentrated for use, 100 c.c. should be diluted to 150 c.c. with distilled water. The dilute solution will keep.

Picric acid is an excellent protein precipitant, but for the detection of albumin in urine, it must be used in a concentration that will not give false positive reactions. After careful study the quantity given in the formula was found to meet this requirement. The citric acid will prevent the possible precipitation of phosphates. The magnesium sulphate, which will precipitate serum globulin, is used primarily to give the solution a high specific gravity. This prevents diffusion of the reagent with the urine, the zone of contact remaining well defined.

REAGENT *

Picric acid, wet	10 gm.
Magnesium sulphate	400 gm.
Citric acid	20 gm.
Distilled water	1,500 c.c.

* Picric acid, wet, is the product ordinarily supplied, containing 20 per cent. added water for safety in shipping. The magnesium sulphate used is the U. S. P. crystalline salt.

TECHNIC

An ordinary, heavy wall culture tube, 150 by 15 mm., and a piece of glass tubing 20 cm. long, with a diameter of 6 mm. and 1 mm. wall are procured. The reagent is poured into the test tube to a depth of about 4 cm. It is advisable to use the centrifuged specimen, as the organized elements, in suspension, may give a false reaction, the same as with the heat test. The glass tube is introduced into the specimen to a depth of about 2 cm. The end of the tube is closed with the finger, as in using a pipet, and the tube is withdrawn and introduced into the reagent so that the level of the urine is slightly lower than that of the test solution. The finger is now removed and the urine and reagent will rise in the tube, giving a distinct zone of contact without diffusion. The tube may be removed to facilitate the reading, the finger being held between the light and the tube. In the presence of albumin a white ring will form, the intensity indicating the quantity. Faint traces, as found by the heat test, may be easily detected by this method. After each test the tube should be rinsed by being dipped in water. If the reagent in the test tube becomes cloudy, it should be discarded, as it is essential that the reagent and urine be clear. With a little experience, an estimation of the quantity of albumin can be as readily made as with the heat test.

RESULTS OBTAINED

A series of 725 specimens was examined by the heat test and with the new reagent. The sediment was also examined as a check on the chemical results. For convenience, the new reagent will be referred to as Solution B.

TABLE 1.—RESULTS OF TESTS

Negative.	Positive.	Positive	
		with Heat.	with Solution B
500	225	205	213

It will be noted from Table 1 that out of a total of 725 specimens, 225, or 31.03 per cent., were positive with either heat or Solution B, or both. Of these, 205, or 28.27 per cent., were positive with heat, and 213 or 29.38 per cent., were positive with Solution B. Out of the 225 positive specimens, twenty gave reactions with B which were negative with heat. With the heat test, twelve were positive which failed to react with the new reagent.

TABLE 2.—VARIATIONS DISCLOSED BY MICROSCOPIC EXAMINATION

Sediment—	Positive with Heat. Negative with Solution B.	Positive with Solution B. Negative with Heat.
Pathologic	8	14
Normal	4	6

The microscopic examination of all specimens confirmed the chemical results, except in a few cases, as noted in Table 2, in which it will be seen that positive reactions were obtained by both tests, in a few cases, in which the sediment was normal. Also a few pathologic specimens failed to react with one of the reagents, either heat or solution B. These variations were all found in urines showing only a trace or faint trace of albumin, and are to be expected.

Military Medicine and Surgery

THE PREVAILING PANDEMIC OF INFLUENZA

J. J. KEEGAN, M.D.
Lieutenant (Junior Grade), M. C., U. S. Navy
CHELSEA, MASS.

During the past two weeks, August 28 to September 11, there has begun a severe and rapidly spreading epidemic of influenza in the First Naval District. More than 2,000 cases have been reported in these two weeks, and there are indications of a rapid spread of the infection. This is undoubtedly the same disease which, first heard of in Spain last spring, and hence called Spanish influenza, has in recent months spread over nearly all of Europe, including Germany, Italy, France, England and Ireland, attacking from 30 to 40 per cent. of the people. The outstanding feature of this epidemic is its high degree of communicability; in fact, in pandemics of this nature, influenza is the most contagious of all infections. The last pandemic (1889-1890) also moved from east to west along the lines of travel. We, therefore, have every indication that this outbreak will soon spread all over the United States. It doubtless has been carried to this country by patients or carriers aboard vessels. In fact, definite histories to this effect have been obtained from officers aboard vessels.

The disease is similar to the familiar endemic influenza, except that it is often more severe, the complications are more frequent and serious, and it shows an extraordinary degree of contagiousness. The number has increased to more than 2,000 within two weeks, in spite of early recognition and reasonable precautionary measures. It has attacked many of the physicians, nurses and hospital apprentices, thus unduly taxing the hospital service, in spite of the use of gauze masks and other precautions by all those in contact with the patients.

CHARACTERISTICS OF THE DISEASE

The incubation period is from one to two days. This was demonstrated by the first cases that developed in the hospital staff after the arrival of the first group of fifty patients. These patients were received Thursday afternoon, August 28, from the receiving ship at Commonwealth Pier, Boston. Blood cultures, blood counts and throat cultures were immediately taken by the laboratory officers, one of whom was suddenly taken sick with the disease the following Saturday morning. Another medical officer, who made the first physical examinations on Thursday, was also sick Saturday.

The onset is very sudden; the patient sometimes passing from an apparently well condition almost to prostration within one or two hours. There is no complaint of sore throat at any time, and no initial localized symptoms. In a few cases the patient attributes the attack to a slight sore throat or ill feeling a few days previously, but the majority give no such history. The fever rises rapidly to from 101 to 105 F. (38.3 to 40.6 C.), the patient usually complaining of severe headache, weakness, general malaise and pains of varying severity in the muscles and joints, especially in the back. As frequently described, the patient feels as though he had been beaten all over with a club.

The course is fairly constant. The patient lies in bed in a semistuporous condition, doubled up, with the covers pulled tightly over his head and neck. There are alternating chilly and warm sensations, but no paroxysmal chill. The face is flushed, the pulse from 100 to 120, the respiration from 20 to 30, the temperature from 101 to 105 F. A few have nausea and vomiting. Epistaxis is not uncommon. There are usually no gastro-intestinal symptoms, the tendency being toward a slight constipation.

After these initial symptoms, which are quite constant, a remission frequently occurs in the morning of the second or third day. In a small percentage of the cases the temperature may continue normal, with recovery. More frequently there is a secondary rise of temperature following the remission, accompanied by a coryza and slight bronchial cough. It is during this period that the disease probably is most contagious, being transmitted almost entirely by direct contact, and by droplet infection within a radius of a few feet.

TABLE 1.—LEUKOCYTE AND DIFFERENTIAL COUNT OF EARLY CASES FROM ONE WARD

Cases	White Blood Cells	Poly-morpho nuclears	Lym-pho-cytes	Large Mono-nuclears	Transi-tionals	Eosino-phils	Baso-phils
1	6,200	76	20	2	2		
2	6,800	65	38	1	5	....	1
8	8,400	77	14	8	6		
4	10,000	73	25	1	1

14	4,600	50	46	2	2		
15	5,200	52	46	2			
10	5,800	48	52				
17	4,200	48	52				
18	6,800	64	28	4	2	2	
19	7,200	72	26	...	...	2	
20	6,800	68	30	...	2		
21	4,600	66	34				
22	5,800	40	56	...	4		
23	8,600	75	24	...	...	1	
24	7,200	78	16	4	2		
25	4,400	56	36	4	4		
26	4,200	68	32				
27	5,000	70	28	2			
28	5.400	56	43	...	1		
Average	6,700	63.7	33.3	1.2	1.2	0.21	0.035

Following this secondary rise, the temperature in uncomplicated cases gradually returns to normal within a week, but the patient is usually still coughing, and feeling rather weak. It requires another week of convalescence before returning to duty is advisable, and then the patient fatigues very easily, and shows distinct effects of the infection. Relapses have not occurred in the short period covering this report.

The laboratory findings in the cases described above are rather constant and characteristic. Blood cultures taken at all stages of the disease have been negative. Improved technic may change this result, but this now appears doubtful, for the disease seems to be a toxemia. The white blood cell count in uncomplicated cases is below normal. The differential leukocyte count is essentially normal. Table 1 illustrates thirty representative cases, taken in one ward as the patients entered in the various stages of the disease, from the first to the third or fourth day. The urine in fully two thirds of the cases shows a faint trace of albumin, and numerous granular and hyaline casts. No case of nephritis has developed. The urine is characteristic of a severe febrile and toxic disease. Table 2 shows the significant urinary findings in the cases of one ward, as they entered.

The remaining 5 to 10 per cent. of the patients in this epidemic develop a very severe and massive bronchopneumonia. Of the ninety-five cases of pneumonia in the hospital developing from the influenza, thirty-five patients have died, and another fifteen or twenty are desperately ill. This would indicate a final mortality of from 60 to 70 per cent. In a case of progressive or extensive involvement, the patient rarely recovers. The bronchopneumonia appears as a continuation or extension of the bronchitis, present in a large percentage, so that there is rarely any remission of the symptoms after the second or third day, and physical signs of pneumonia develop. The consolidation appears most frequently in the right inferior lobe, just medial to the inferior angle of the scapula. The same tendency has been noted in pneumonias in general, but especially in bronchopneumonias. It probably is due to the anatomic relation of the right bronchus, this bronchus presenting a larger opening than the left within the trachea, and being shorter, larger and in more direct line with the trachea than the left, so that gravity and direct extension would favor the first appearance of involvement in the posterior upper portion of the right inferior lobe.

TABLE 2.—URINE EXAMINATIONS FROM EARLY CASES OF ONE WARD

Cases	Specific Gravity	Albumin*	Microscopic
1	1.029	Neg.	
2	1.025	F. T.	Many hyaline and granular casts

22	1.028	V. F. T.	Numerous hyaline and granular casts

* Abbreviations: Neg., negative; F. P. T., faint possible trace; V. F. T., very faint trace; F. T., faint trace of albumin.

The bronchopneumonia extends very rapidly to the left inferior, the right upper and middle lobes, and finally to the left superior lobe, so that in many of the earlier cases death is distinctly one of asphyxiation. In cases of longer duration a severe toxemia is evident. The leukocyte count is very variable, frequently maintaining the leukopenia that is characteristic of the initial disease (Table 3). This persisting leukopenia can usually be interpreted as due to an uncomplicated influenza bacillus pneumonia, since this organism apparently calls forth no defensive leukocytosis in the circulating blood. The necropsies have corroborated this interpretation. The accompanying chart illustrates such a case. More frequently, however, there is a leukocytosis, this representing a secondary infection with either the pneumococcus or the streptococcus.

A purulent effusion or empyema does not develop in the pleural cavity. This may be due partly to the short duration of the pneumonia before death. In the terminal stages, with embarrassed and failing circulation, there is frequently a serofibrinous effusion into the pleural cavity, most frequently unilateral and on the right side, varying in amount from 100 to 1,000 c.c. The cell count of this fluid is rarely over 5,000 per cubic millimeter, chiefly polymorphonuclears. This fluid usually contains pneumococci or streptococci.

The gross pathology revealed at necropsy shows a massive and largely confluent bronchopneumonia, thus frequently simulating a lobar pneumonia. In the early cases, however, and in the more recent areas of the later cases, the bronchopneumonic type is very evident. The cut surface has a mottled, firm, granular appearance, each bronchiole standing out as a grayish area, with intervening dark red alveolar tissue. The coarse, nodular consolidation of a typical bronchopneumonia is rarely present. A large quantity of blood exudes from the cut surface. In the more prolonged cases this rather uniform bronchopneumonic consolidation passes through a more firm, gray stage, and then to a characteristic condition of diffuse and confluent small abscesses. These may be seen from the surface as flat, grayish yellow areas maintaining the markings of the lung lobules. Creamy, grayish yellow pus exudes from the cut surface in all regions, leaving a slight reticulum of necrotic lung tissue.

The remaining organs are essentially normal in appearance, except for a moderate degree of congestion. The heart in one case was acutely dilated. The liver and spleen are slightly enlarged. The spleen rarely shows the enlarged, soft, flabby condition so frequent in other forms of pneumonia. The cut surface is firm, dark red, smooth, and with indistinct markings. The kidneys are congested but otherwise of normal appearance. Microscopic examination of the tissues has not been completed, but will be made the subject of a separate report on the pathology of the disease, this being quite distinctive in the lung tissues.

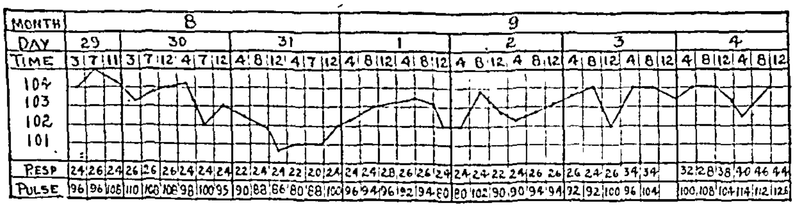
BACTERIOLOGIC FINDINGS

The bacteriology of this epidemic has been the subject of special study, on account of the unusual severity and communicability of the disease, and its disputed relation to the common endemic disease known as influenza. The influenza bacillus has been generally accepted as the etiologic micro-organism of influenza. Pfeiffer discovered the influenza bacillus in 1892, two years after the great pandemic of influenza of 1889-1890. This pandemic spread rapidly over all parts of the world, attacking between 40 and 50 per cent. of the inhabitants and having a comparatively high mortality. The present pandemic is undoubtedly of the same character and is in all probability the same disease.

The reports of the bacteriology of the present pandemic in Europe serve only to confuse on account of their incompleteness. THE JOURNAL[1] and the London *Lancet*[2] have given the most recent reviews of the conflicting opinions in Europe, including the opinions of the French and the German investigators. The influenza bacillus was found only occasionally. Streptococci, pneumococci and the *Micrococcus catarrhalis* were recovered more frequently from the throat and sputum and occasionally from the blood. Little, Garofalo and Williams[3] selected a pleomorphic gram-positive coccus as the probable etiologic micro-organism, this in all probability being a pneumococcus of the mouth. Gotch and Wittingham[4] are inclined to attribute the disease to the *Micrococcus catarrhalis.*



Clinical chart of an uncomplicated influenza bacillus pneumonia. The patient died September 4. Leukocyte Counts:

	Influenza	Pneumonia	
	August 29	September 1	September 3
Total	6,800	8,800	5,200
Polymorphonuclears	68	64	74
Lymphocytes	30	32	26
Transitionals	2	4	..

In the present epidemic in the naval stations of Boston, throat cultures were made, streaked on blood agar plates, from more than 100 cases, and similar cultures made from washed selected bronchial sputum, in search of the influenza bacillus or other predominating organisms. As a control, a similar number of blood plate throat cultures were taken from convalescent hospital patients. In both lots the predominating organism was a gram-positive diplococcus, with a considerable green area surrounding the small gray colonies and frequently marked pleomorphism noted on smear, probably corresponding to the pleomorphic organism described by Little.[3] Approximately pure cultures of a hemolytic streptococcus occurred in 4 per cent. of the influenza cases, in comparison with 20 per cent. of the control cases. A few colonies of hemolytic streptococcus were found in an additional 16 per cent. of the influenza cases. In the influenza plates there were numerous small, colorless colonies, some of which stained typically as influenza bacilli. But similar colonies could be found in many of the control cultures, and they were by no means constantly found in either lot, so that no conclusions could be drawn from this source. These negative findings in throat cultures may be explained by the difficulty of isolating the influenza bacillus from mixed cultures. Also, it is probable that the focus of influenza bacillus infection is not in the pharynx, but is located in some recess of the nasal cavity, explaining the negative throat symptoms. In this respect the influenza bacillus would be likened to the meningococcus, which selects the posterior nasopharynx for most abundant growth, and the diphtheria bacillus, which usually selects the supratonsillar fossa for its primary focus.

Mouse inoculation of washed selected sputum was made in numerous cases. There was no uniformity of results. Almost all possible organisms were recovered in pure or mixed cultures, pneumococci, *Streptococcus viridans, Streptococcus hemolyticus, Micrococcus catarrhalis* or the influenza bacillus, or the mouse recovered. The sputum of the bronchopneumonia patients usually is not the tenacious, fibrinous, blood-stained sputum of pneumococcus pneumonia, but a purulent, opaque, greenish or yellowish red sputum, showing on smear a predominating gram-positive diplococcus. It resembles more that of the streptococcus pneumonias of the past winter.

The smears and cultures from the lung punctures and necropsies furnished the best evidence of the nature of the infectious process. Table 4, of the results of cultures taken directly from the lungs, shows that the influenza bacillus occurred either in pure or mixed culture in 82.6 per cent. of the twenty-three cases studied thus far. The only cases in which it did not occur were four, in which there were pure cultures of a hemolytic streptococcus. In six cases, or 31.6 per cent. of the positives, there were pure cultures of the influenza bacillus. It should be noted that these pure cultures were all in pneumonias of short duration, none of more than four days' and two of only two days' duration. The influenza bacillus was found in no case in the pleural fluid or in the heart's blood (Table 5). In direct smears from the lung tissue a very small coccobacillus, characteristic of the influenza bacillus, could be identified in many cases with a methylene blue stain, but with difficulty with a gram stain on account of its small size and poor staining qualities. By this means pure cultures and predominant cultures of the influenza bacillus can successfully be predicted from lung smears. It is found almost entirely within polymorphonuclear leukocytes, and in considerable numbers within individual cells, but not within all cells.

The most common secondary invader is the pneumococcus, occurring in thirteen of the twenty-three cases tabulated, or 56.5 per cent. Six of these, 46.1 per cent., were the Type II pneumococcus, two the Type III pneumococcus, and five the Type IV pneumococcus. One patient had both a Type III and a Type IV pneumococcus infection. The differentiation of the Type IV pneumococcus and the pleomorphic forms of the *Streptococcus viridans* is not without difficulty, and some of these on further study may be found to fall within the *Streptococcus viridans* group. Bile solubility tests of broth cultures were not found very reliable for identification of the pneumococci, some of the fixed types, identified by agglutination, not showing a distinct bile solubility. Hence morphology was relied on in the doubtful Type IV cases.

TREATMENT

This frequency of the pneumococcus, especially the Type II pneumococcus, brings up the question of the possible value of sputum typing and antipneumococcus serum therapy in these pneumonias. First, it is noteworthy that no case of a Type I pneumococcus has thus far occurred in the outbreak in this locality. This indicates that the infecting pneumococcus is a common mouth inhabitant, since Type I pneumonias are rarely met at the present time. The second point of interest is the fact that no pure infection with the pneumococcus has yet occurred. In every case of pneumonic complications the influenza bacillus was also recovered from the lung cultures, frequently in as great numbers as the pneumococci or in greater numbers. Considering the presence of six cases of pure influenza bacillus pneumonia, the interpretation is that the influenza bacillus is the primary invader in every case, sufficient in itself to cause a rapidly fatal pneumonia, and that the pneumococcus acts entirely as a secondary or terminal invader. It is questionable if serum therapy, and especially Type II antipneumococcus serum, would have much influence altering the course of the disease.

However, sputum pneumococcus grouping and antipneumococcus serum therapy should be tried in selected cases. By selected cases is meant those in which the patients are bringing up typical pneumococcus sputum and have a marked leukocytosis, showing that this organism is the predominating one. Indiscriminate routine typing of all cases that show a patch of bronchopneumonia is an impossible task in the present emergency, as well as of doubtful value, for in all cases at necropsy there is found a distinct bronchopneumonia, although at times of such massive and confluent character as to be distinguished with difficulty from lobar pneumonia. A significant feature recently noted is that a separate type of infection may occur in the two lungs, one being both an influenza bacillus and a pneumococcus infection, while the other lung may give a pure culture of a pneumococcus, a streptococcus or a *Micrococcus catarrhalis*.

The hemolytic streptococcus occurred in five of the twenty-three cases, or 22.7 per cent., and in four of these it was the only organism present. As noted previously, these four cases were the only ones of all twenty-three in which the influenza bacillus was absent. This is significant in view of the known extremely invasive properties of the *Streptococcus hemolyticus* and its tendency completely to obscure a primary infecting micro-organism. The low percentage of hemolytic streptococci as secondary invaders in the bronchopneumonias of this disease, compared to their incidence in the postmeasles bronchopneumonias of the past winter, perhaps reflects the low percentage of pure hemolytic streptococci found in the throat cultures of a group of these men as they entered the hospital, being only 4 per cent.

The *Micrococcus catarrhalis* is a fairly frequent secondary invader found in the lungs and in one instance in pure culture in the heart's blood. The *Staphylococcus aureus* occurs infrequently and in small numbers.

THE INFLUENZA BACILLUS

The interpretation of these bacteriologic findings is that the influenza bacillus is the primary invader in all cases of pneumonia accompanying this outbreak of influenza. This pneumonia is always a bronchopneumonia and is frequently complicated by a secondary infection with the pneumococcus or the streptococcus, and less frequently with the *Micrococcus catarrhalis* and the *Staphylococcus aureus*. Separate, double or triple secondary infections may occur.

This tendency of the influenza bacillus to grow in symbiosis or in an ancillary relation with other organisms in the lungs is not necessarily due to the more virulent nature of the secondary invaders, but may be due to a well-recognized property of the influenza bacillus to grow much more luxuriantly in the presence of certain other organisms, especially the staphylococcus, but also the pneumococcus, the streptococcus and numerous other organisms. This is most strikingly illustrated in plate cultures of the influenza bacillus, by the colonies in the vicinity of a staphylococcus colony. These colonies grow to giant size, from 2 to 3 mm. in diameter, in comparison with the remote influenza colonies which remain barely visible at the end of four or five days.

The influenza bacillus in this study was identified by the small size and colorless appearance of the colonies, which were almost imperceptible at the end of twenty-four hours, and then visible only by reflected light. Around a staphylococcus colony they have a distinct gray color on account of their larger size. They are moist and easily removed with a platinum wire and readily emulsify in salt solution. Microscopically, the influenza bacilli appear as exceedingly small gram-negative coccobacilli. There are no specific agglutination or fermentation tests available for further identification of the influenza bacillus. It is nonpathogenic for all laboratory animals except in a few reported instances of monkey inoculation in which the characteristic disease was reported to have resulted.

A fixed strain of the influenza bacillus, such as this organism must be, to act in such a virulent and pandemic manner, has never previously been available for the study of specific serum reactions. The bacillus was not discovered until after the great pandemic of 1889-1890, and there has been no similar pandemic of influenza since, until the present. Work on the specific serum reactions of this strain of the influenza bacillus is now in progress, and it is hoped that specific reactions will be found, probable toxins demonstrated, and possible antitoxins or vaccines prepared that will prove of use in prophylaxis, or in clearing up the chronic reinfective condition so frequently remaining after the first acute symptoms.

The focus of the primary infection most certainly is in the upper respiratory passages, but it gives rise to practically no localizing symptoms during the first day or two of the disease. Then it attacks the nasal mucosa and usually the bronchi. A sore throat is never complained of in the typical cases. Other organisms usually predominate in the pharynx. Further study should locate more specifically the primary focus of infection and the location in carriers.

Speculation as to the probable cause of the beginning of this pandemic of influenza suggests that it may bear some relation to the congregation of such enormous numbers of troops in Europe; that an original slightly pathogenic influenza bacillus, by passage through many individuals in a short period, has become a fixed, highly pathogenic strain of the influenza bacillus.

In the beginning of this study of the etiologic organism of the prevailing pandemic of influenza, an experiment was performed in conjunction with Dr. M. J. Rosenau, director of the Naval Hospital laboratory, on nine volunteers from the Deer Island Naval Training Camp. These men had not been exposed to the disease, there having at that time been no cases at Deer Island. The experiment was for the purpose of determining whether or not the disease was due to a filtrable virus. Certain features of the onset and course suggest strongly a similarity to dengue, yellow fever, trench fever and pappataci fever.

The experiment consisted of introducing the filtrate of the washings from the nose and throat of two cases of influenza into the anterior nares of nine volunteers. The influenza cases selected were typical, with definite history of recent exposure. One was in the second day of the disease and the other in the fourth day. The nose and throat of each patient was washed and gargled with 75 c.c. of sterile physiologic sodium chlorid solution. Throat swabs and sputum were added to the separately collected washings. Each was shaken with beads in a sterile bottle and filtered through a Mandler diatomaceous earth filter by means of a water vacuum pump. One filter had a positive pressure value of 9 pounds and the other of 12 pounds. Cultures were made from the clear filtrates for control. The filtrates were then carried to Deer Island, where about 0.5 c.c. was introduced into the anterior nares of each of the volunteers, five receiving the filtrate from one case and four from the other. Three and one-half hours had elapsed from the time of obtaining the nasal washings to the time of the nasal instillation. The control cultures were negative for bacterial growth, and none of the nine volunteers have shown symptoms of the influenza during ten days of isolation.

These men of the U. S. Navy are especially to be commended for their fine spirit in being willing to take chances of serious sickness for the sake of advancement of knowledge of the disease. The nature of the experiment and the possibility of serious consequences were fully explained to them. Their names are: J. E. Kiley, F. J. Hogan, F. B. O'Neill, P. G. Woods, L. C. Berg, H. L. Robertson, T. E. Null, T. A. Walker and H. A. Maronowitz.

In the other portion of the work thanks are due Dr. J. M. Brister, Dr. M. J. Rosenau, Dr. E. W. Goodpasture, Dr. William R. Redden, Dr. F. L. Burnett and Dr. F. N. Rapoport of the U. S. Naval Hospital, Chelsea, Mass., medical staff, for their assistance in examination and report of the cases.

SUMMARY

A rapidly spreading pandemic disease was first recognized at the U. S. Naval Hospital, Chelsea, Mass., Aug. 28, 1918, the first patients coming from the receiving ship at Commonwealth Pier, Boston. It has been carried to this port from Europe, both by patients and by carriers. It promises to spread rapidly over the entire country, attacking between 30 and 40 per cent. of the population, and running an acute course of from four to six weeks in each community.

This disease is characteristic of the ordinary endemic influenza, but is more severe and much more contagious. It is caused by a specific virulent strain of the influenza bacillus, against which individuals of the younger generation have relatively no immunity.

In from 5 to 10 per cent. of the persons afflicted, it develops into a massive and very fatal bronchopneumonia. This pneumonia is primarily caused by the influenza bacillus, this micro-organism being recovered from 82.6 per cent. of the lungs at necropsy, in 31.6 per cent. of which it is found in pure culture. The pneumonia is frequently complicated by pneumococcus or streptococcus infection.

The disease is characteristic of a sudden and severe toxemia, the influenza not being in the blood at any stage. It is not due to a filtrable virus. This was determined by introduction of the filtrate of nasal and throat washings from two typical cases into the anterior nares of nine volunteers, with negative results.

U. S. Naval Hopital.

Administering the Birth Registration Law.—Administrative history seems to indicate that it is easier to enforce a law on a new subject than it is on one that radically changes existing practices. It is this latter condition that has met most officers in the effort to enforce model birth registration laws. With the enactment of a model registration law in Kansas in 1911 it was found that it was not only necessary to put into active operation the new law, but to break up the old habits of reporting and not reporting.—W. J. V. Deacon, M.D., State Registrar.

INFLUENZA AT NAVY BASE HOSPITAL IN FRANCE*

A. W. HEWLETT, M.D. (San Francisco)
Surgeon, U. S. N. R. F.
and
W. M. ALBERTY, M.D. (Rosedale, Kan.)
Assistant Surgeon, U. S. Navy
EUROPE

The present epidemic of a disease which in its clinical aspects resembles influenza is the most extensive of its kind since the great pandemic of 1889-1890. For several months frequent references have been made in foreign newspapers and medical journals to the prevalence of this epidemic in Spain, France, Switzerland, Germany, Great Britain and Ireland. On the western front both armies seem to have been sufferers. As an example of its military importance, 1,439 cases occurred in a military camp within three weeks,[1] and this appears to have been no very unusual record.

Concerning the infectious cause of the present influenza epidemic there is no unanimity of opinion. The Pfeiffer influenza bacillus has been isolated from a varying proportion of patients; but many observers have failed to find this organism with any regularity.[2] It is quite possible, indeed, that this organism is not responsible either for the present epidemic or for the pandemic of 1889-1890. On account of this uncertainty as to the etiology of influenza, the diagnosis must for the present be based mainly on its clinical and epidemiologic characteristics.

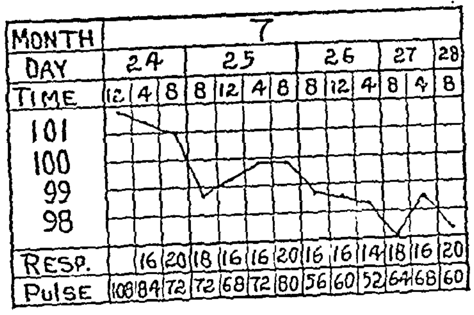

Fig. 1.—Temperature chart of a mild case of influenza.

GENERAL FEATURES OF THE LOCAL OUTBREAK

Before influenza assumed epidemic proportions in this hospital, a number of patients had been admitted who were suffering from complications and sequelae of the disease. No special effort was made to isolate these patients. Occasional cases have developed from time to time in the hospital wards, but at no time has the disease spread to any great number of ward patients.

One of the earlier definite cases among the hospital personnel was that of an officer who had recently returned to the hospital from a city where influenza was prevalent. Following his illness the disease appeared in slow succession among a small number of officers, nurses and enlisted men. It is doubtful, however, if these cases, which were more or less isolated, would have attracted much attention had there not been an epidemic elsewhere or had they not been followed by an explosive outbreak among the hospital personnel.

July 16, 1918, nineteen Hindus, who were from a single vessel and who had just become ill with influenza, were admitted to the hospital. Up to this date very few of our enlisted men had suffered from influenza. On the same day that the Hindus were received, however, two members of the hospital corps became ill. Since an epidemic among the enlisted personnel had been anticipated for some time and since it now seemed imminent, an order was issued by the officer in command that all enlisted men suffering from influenza should enter the hospital as patients. For two and a half weeks the disease spread rapidly through the personnel. The number of enlisted men who were admitted to the hospital during this time was: July 16, two; July 17, one; July 18, three; July 19, one; July 20, two; July 21, four; July 22, seven; July 23, nine; July 24, five; July 25, two; July 26, four; July 27, none; July 28, six; July 29, four; July 30, three; July 31, none; August 1, two; thereafter up to August 20, none. In eighteen days, therefore, fifty-five members of the enlisted personnel suffering from influenza were admitted as patients to the hospital. Including five who had the disease shortly before, the morbidity among the enlisted men was 37 per cent. During these eighteen days, nineteen nurses contracted the disease. These, together with four who had had it shortly before, made a morbidity of 40 per cent. among the nursing staff. Finally, of twenty-nine officers, fifteen had influenza during the epidemic. Of the total personnel at the hospital, 41 per cent. were known to have contracted the disease, and the vast majority of these became ill between July 16 and August 2, inclusive. After August 2 there were no new cases among the enlisted men, one doubtful case among the nurses and one reinfection among the officers. The epidemic had ceased, apparently because all those susceptible to the infection had acquired it.

It is certain that influenza existed in the hospital prior to the admission of the Hindus, and for this reason the epidemic cannot be definitely attributed to their admission. Nevertheless the presence of these patients probably accelerated the spread of the infection, for many of them had a marked bronchitis and it was several days before they could be taught to use sputum cups. Furthermore, an unusual proportion of cases developed shortly after their admission among those nurses and corpsmen who were attached to the ward that contained the Hindus.

Second attacks of influenza in the same individual seemed to occur in six or seven instances. The second attack usually followed several weeks after the first. Since the diagnosis was based solely on clinical findings, and since these do not differ in any characteristic manner from a number of other mild infections, it is not possible to be certain that the two attacks were always due to the same infection. However, we gained the impression that in some instances at least the immunity left by the first attack of influenza did not protect from a second attack of the disease a few weeks later.

CLINICAL CHARACTERISTICS

The subjoined summary of the clinical manifestations of influenza in this small epidemic is based on the records of the nineteen Hindus and the fifty-five members of the enlisted personnel, all of whom had been admitted to the hospital wards. As the disease was more serious among the Hindu patients, a distinction between these and the enlisted men will occasionally be necessary.

---

* From the Medical Service of U. S. Navy Base Hospital No. 2.

[1] Averill, C.; Young, C. G., and Griffiths, J.: The Influenza Epidemic in a Camp, Brit. Med. Jour., 1918, **2**, 111.

[2] Bacteriology of the Influenza Pandemic, Brit. Med. Jour., 1918, **2**, 139. Matthews, J.: Preparing Medium for the Culture of the Pfeiffer Influenza Bacillus, Lancet, *London*, 1918, **2**, 104. Dr. G. D. Barnett made several unsuccessful attempts to demonstrate influenza bacilli in the sputum and nasapharyngeal smears from our patients.

The onset was at times sudden; at other times it was gradual and the patient remained at work for one or more days before he reported ill. The initial symptoms were in most instances headache, backache, malaise, chilliness and pains in the extremities. Several complained of pains in and above the eyeballs. A few of the enlisted men and a considerable number of the Hindus complained of abdominal pain during the first day or two of the disease. Irritation of the upper respiratory tract occurred in about two thirds of the patients. This usually consisted of a dry, hacking cough or of soreness of the throat. Less commonly there was hoarseness, a sense of rawness beneath the sternum, or a cough productive of sputum. The last was the rule among the Hindus.

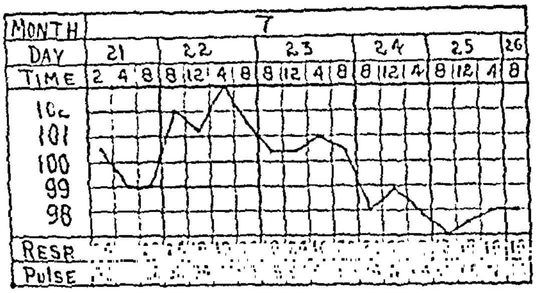

Fig. 2.—Temperature chart of a case of influenza in which the main rise of temperature occurred on the second day in the hospital.

Examination at the onset showed in most instances some reddening of the pharynx, which commonly involved the anterior pillars. The tonsils were rarely swollen, and the glands at the angle of the jaw were not palpable. When the cough was productive, bronchial râles could be heard over the lungs; but otherwise the respiratory sounds were normal. There was no enlargement of the spleen, no swelling of the lymph glands and no abdominal tenderness or rigidity.

Mental dulness and apathy were common, and in some instances the patient was continuously drowsy and slept most of the first forty-eight hours of his illness. In other instances, the headache, backache or pains in the extremities, together with a general irritability, made the days uncomfortable and the nights restless.

Nearly all patients showed considerable fever. Among the Hindus all but one showed a maximum temperature of 103 or over. Among the enlisted men the average temperature was 102, but it varied from a few whose temperature hardly exceeded the normal to one whose maximum was 105.6. In several patients who developed the disease in the hospital wards, the temperature rose abruptly; but it may also rise gradually. In thirty enlisted men the temperature was highest on the day of admission to the hospital, in seventeen it was highest on the second day, while in one it was highest on the third day. In uncomplicated cases the fever lasted from one to six days, with an average duration of about three days. The fall was usually by lysis. When the fever lasted more than six days in our patients, bronchitis or bronchopneumonia was present. Representative temperature charts are reproduced herewith.

The pulse rate was accelerated but usually not in proportion to the rise of temperature. For example, the temperature of 105.6 was accompanied by a pulse rate of 104, while pulse rates below 100 with temperatures above 103 were common. Among the Hindus, the pulse rates were somewhat more rapid than among the enlisted men; but they were still slow relative to the temperatures. When serious pulmonary complications were present, the pulse became rapid. It seemed to us that the pulse furnished a better indication of the severity of the infection than did the temperature.

Leukocyte counts made at the onset in seven uncomplicated cases showed from 5,000 to 8,000 to the cubic millimeter. In three Hindus who subsequently developed bronchopneumonia the counts were 8,600, 9,200 and 10,000. Faint traces of albumin were found in thirty of forty urines examined during the early stages of the disease. In two others there was a heavy cloud of albumin. Casts were found in eight urines. Later examinations in a number of these cases showed a normal urine after subsidence of the infection.

Convalescence was commonly marked by an unusual degree of prostration and by unusual exhaustion on slight exertion. These symptoms usually passed off in from three to five days after the temperature had become normal, but in a few instances they lasted a week or more.

The only serious complication among these patients was bronchopneumonia. This was suspected in two or three of the hospital personnel. It was definitely diagnosed in four of the nineteen Hindus, the diagnosis being based on the considerable number and persistence of râles, the protracted fever, the rapid pulse rate and the serious character of the illness. In only one of these patients were the usual signs of consolidation demonstrable. Of these four patients, two died. These were the only deaths in this local epidemic.

We have had the opportunity to observe the complications and sequelae of influenza in a considerable number of patients who have been sent to the hospital. Without going into detail, it may be said that the most common sequelae observed were infections of the lungs and pleurae, particularly fibrinous and serofibrinous pleurisy, empyema, persistent bronchitis and bronchopneumonia. Prostration and continued cough have frequently given rise to a suspicion of pulmonary tuberculosis. Less common have been cardiac disturbances which were characterized by breathlessness, palpitation, precordial pain and rapid pulse. In a number of patients the symptoms have been those of neurasthenia or less commonly of a marked and persistent general asthenia.

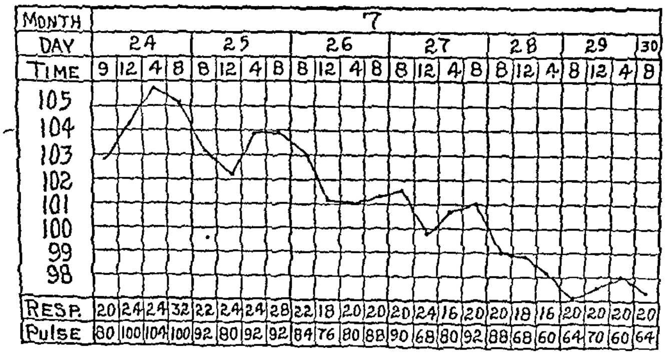

Fig 3.—Temperature chart of a severe but uncomplicated case of influenza.

The treatment used was expectant and symptomatic. With the onset of fever the patient was sent to bed and was kept there until the temperature had been normal for at least forty-eight hours. If pains in the head, back and extremities were troublesome, acetylsalicylic acid was given in doses of 15 grains every three hours until six doses had been taken. If the patient could not sleep, 5 grains of barbital were given at bedtime. Oily sprays lessened the irritation in the upper air passages. By these means the early discomforts were diminished. Since the chief danger of the infection arises from complications and sequelae, care to avoid these should be taken. The spread of bronchopneumonia is probably increased when many patients are treated in confined quarters. Under such circumstances special precautions should be taken against contact and droplet infection. On account of the danger of cardiac and neurasthenic sequelae, convalescence should be prolonged until the patient can carry on his usual duties without fatigue.

CONCLUSIONS

The present widespread epidemic of influenza is comparable to that which swept over the world in 1889-1890. The percentage mortality is very low, but the total mortality is probably considerable on account of the high morbidity. Under unfavorable conditions of lessened individual resistance and overcrowding, the percentage mortality may also be high. For example, a ship's surgeon informed us that of fifty Hindus who contracted the disease, he lost fifteen with pulmonary complications.

The clinical features of this disease, together with its rapid spread to a large number of individuals, give it a definite character. The clinical features alone do not suffice to mark it off clearly from the sporadic cases of "influenza" that occur from time to time in every community. If the disease continues to spread in a manner comparable to that of 1889-1890, an opportunity to study its etiology will be given to bacteriologists in the United States.

Training the Disabled in Great Britain and Ireland.—According to the *Vocational Summary*, published by the Federal Board for Vocational Education, the British ministry of pensions publishes each month a list of training courses for the reeducation of disabled soldiers in the United Kingdom. Training courses have been provided in many different lines, and in many different communities. The courses are given by public and private schools, colleges and institutes in every section of the country, as well as in factories and workshops. The list of courses for May, 1918, printed in the *Summary* shows a list of subjects of the greatest variety taught in many communities. This plan is of interest to the people of the United States who are preparing a national scheme of reeducation under the Smith-Sears Act for vocational training.

LABORATORY AS AID IN CONTAGIOUS DISEASE ADMISSIONS IN CANTONMENT HOSPITALS

A. B. MORRILL, M.D. (Chicago)
Major, M. C., U. S. Army
A. E. F.

Early last winter it was found at Camp Grant that the receiving officer, who admitted all patients, could not give time for the necessary examination of contagious cases, and measles and scarlet fever patients were occasionally put into clean wards, tying up these wards for long periods of time with quarantine regulations. For this reason the contagious disease department took over the admission of all contagious cases.

TABLE 1.—AVERAGE WHITE COUNT ON ADMISSION

Diseases	Number of Cases	Average White Count
Measles	346	7,539
German measles	19	9,777
Mumps	488	9,415
Scarlet fever	91	18,926
Streptococcus sore throat	33	17,484
Whooping cough	3	20,433

All patients were stripped to the waist and examined. In the definite cases, patients were sent to the proper wards, and in doubtful cases to the observation wards. Difficulty soon developed in properly grouping the following types of cases: (1) infections in the incubation period of a second infection; (2) double infections, in which, for instance, a measles eruption masked a scarlet fever efflorescence; (3) cases that were apparently one infection but in reality were another. It was found that the leukocyte count taken after admission to the ward readily differentiated most of these cases.

The suggestion was therefore made that the white blood count for the differentiation between these diseases be made in the receiving office. In this way a large majority of these patients could be sent directly to the proper ward without an intermediate delay of a day or two in the observation wards. With this idea in mind a unit laboratory was placed in the receiving office, and a leukocyte count was made in all doubtful cases. A larger number of cases proved to be doubtful than was at first apparent, so that it became expedient to make counts in all cases. Before this procedure was instituted, the error made in making the immediate diagnosis was about 5 per cent. of all cases; the white count reduced this error to

approximately 1 per cent. It also increased the number of cases in which an immediate diagnosis could be made. This cut down the number of patients that it was necessary to send to the observation wards.

In the laboratory of the receiving office, cultures and cover glass smears are made from all sore throats to determine the presence of the diphtheria bacilli. In all cases of sore throat with exudates that show organisms resembling the diphtheria bacilli in the smears, the patients are immediately given antitoxin. The administration of antitoxin in other cases can usually await the examination of cultures. Because of the known susceptibility of scarlet fever patients to diphtheria, it is important that no throats harboring the diphtheria bacilli should be allowed to remain in the scarlet fever ward; and to avoid such cross-infection, in all scarlet fever cases smears are taken and cultures made in the receiving office. A Schick test should be made in all cases of sore throat, and it is often a valuable aid in differentiating between a true diphtheria and a diphtheria carrier. This is especially true when a streptococcus exudate clouds the picture.

This laboratory has also proved to be a convenient place for obtaining the blood for routine Wassermann tests, and recently has been of value in obtaining a series of throat cultures to determine the frequency of the hemolytic streptococcus.

Table 1 shows the average white counts in the various diseases on admission. It contains both uncomplicated and complicated cases with the exception that unquestionable cases of double infection were omitted. Many cases of measles and some cases of mumps were complicated by the hemolytic streptococcus, which elevated the white count. Therefore these diseases will show a higher average than a series of uncomplicated cases. The table is considered of value, however, because it shows the figures the receiving officer actually has to consider in making his disposition of cases.

Out of 476 cases of measles, 66 per cent. showed Koplik's spots on admission, which was usually on the first day of eruption.

These examinations led to the following general conclusions:

Measles patients with counts of more than 10,000 and mumps patients with counts over 12,000 had a complication that demanded a careful diagnosis before they were sent to the wards. In a small series of nineteen cases, German measles averaged a higher count than true measles. Many mumps patients have a leukopenia of from 5,000 to 7,000. An orchitis elevates the white count in this disease by an increase of the mononuclear cells. There was little difference in the white counts in streptococcus sore throat and scarlet fever, although scarlet fever averaged slightly higher.

It might be objected that these laboratory tests would undesirably lengthen the process of getting the patient to bed. Practically this did not occur. If it did occur, it could easily be remedied by putting more workers in the laboratory. Installation of small cubicles will maintain the technic of the masking system, while the patient is unmasked for throat cultures, etc. These cubicles should be made of wood and sheet metal and covered with white enameled paint, so that they can be frequently disinfected with soap and water.

Table 2 shows the amount of work done by this unit laboratory at Camp Grant.

New and Nonofficial Remedies

The following additional articles have been accepted as conforming to the rules of the Council on Pharmacy and Chemistry of the American Medical Association for admission to New and Nonofficial Remedies. A copy of the rules on which the Council bases its action will be sent on application. W. A. Puckner, Secretary.

CHLORCOSANE.—A liquid, chlorinated paraffin containing its chlorine in stable (non-active) combination.

Actions, Uses, Dosage, Physical and Chemical Properties.—See The Journal, Feb. 16, 1918, p. 459.

Chlorcosane-Squibb.—A brand of chlorcosane.

Manufactured by E. R. Squibb & Sons, New York. No U. S. patent or trademark.

THROMBOPLASTIN SOLUTION-ARMOUR.—An extract of cattle brain in physiological sodium chloride solution prepared according to the method of Hess. It complies with the description of Solution Brain Extract (New and Nonofficial Remedies, 1918, p. 138).

Action and Uses.—See general article, Fibrin Ferments and Thromboplastic Substances (Kephalin) (New and Nonofficial Remedies, 1918, p. 136).

Dosage.—See Solution Brain Extract (New and Nonofficial Remedies, 1918, p. 138). Thromboplastin solution-Armour is marketed in 25 Cc. vials which bear an expiration date, after which time the contents should not be used.

Manufactured by Armour & Co., Chicago. No U. S. patent or trademark.

One part thromboplastin solution-Armour will coagulate 100 parts of oxalated blood plasma in less than one minute when tested as follows:

To 0.5 Cc. thromboplastin solution-Armour is added 24.5 Cc. physiological sodium chloric solution and the mixture shaken until a uniform emulsion results. Of this suspension 5 Cc. is mixed in a graduated cylinder with an equal volume of blood serum. To this is added 10 Cc. of oxalated blood plasma (1 Gm. sodium oxalate in 100 Cc. of water, added to 900 Cc. of fresh blood) and mixed by inverting the cylinder twice. The mixture is rapidly transferred to a shallow dish; it should coagulate in less than one minute. For this test, all solutions must be made freshly and the temperature of the liquids maintained at 38 C.

DESICCATED CORPUS LUTEUM-ARMOUR (See N. N. R., 1918, p. 237).

The following dosage form has been accepted:

Corpus Luteum Capsules, 2 Grains.—Each capsule contains desiccated corpus luteum-Armour 2 grains.

SALIPYRINE (See N. N. R., 1918, p. 275).

The following dosage form has been accepted:

Salipyrine Tablets, 7½ Grains.—Each tablet contains salipyrine 7½ grains.

ANTIPNEUMOCOCCUS SERUM (See The Journal, June 1, 1918, p. 1599).

The Gilliland Laboratories, Ambler, Pa.

Antipneumococcic Serum, Type I.—Marketed in vials containing 50 c.c.

PHENYLCINCHONINIC ACID, U. S. P. (See N. N. R., 1918, p. 269).

Phenylcinchoninic Acid-Abbott.—A brand of phenylcinchoninic acid, U. S. P.

Manufactured by the Abbott Laboratories, Chicago, under U. S. patent No. 1,075,171 (Oct. 7, 1914; expires 1930) by license of the U. S. Federal Trade Commission.

PARRESINE (See N. N. R., 1918, p. 247).

The following dosage form has been accepted:

Parresined Lace-Mesh Surgical Dressing.—Net mesh gauze impregnated with and containing from 45 to 50 per cent. of parresine.

HALAZONE (See N. N. R., 1918, p. 159).

Halazone-Squibb.—A brand of halazone. Sold only in the form of tablets (see below).

Halazone-Squibb Tablets, 1/16 Grain.—Each tablet contains halazone-Squibb 1/16 gr., anhydrous sodium carbonate 1/16 grain and sodium chloride 1⅝ grains.

SATURDAY, SEPTEMBER 28, 1918

THE DAILY PRESS AND THE "FUTILITIES OF CONTEMPORARY SCIENCE"

The American public has so long been accustomed to accept the daily press as its mentor in all things which concern human welfare that the pronouncements of its printed columns are sometimes given an undeserved consideration. However sound and enlightening the almost infinite variety of items published in the newspapers may be as a rule, however convincing and worthy the editorial notices may appear when they analyze the current problems of politics, economics, finance or literature, it not infrequently happens that the reputation of science suffers. Our great metropolitan dailies attempt to secure experts in the domain of so-called "humanistic" studies to guide them in public expression of policies or achievements. All too often science is treated as something apart from the worthier interests of the thinking public; and as a consequence the presentation of scientific achievement often occurs in a crude way that makes errors of statement glaring to the intelligent, or else degrades reports of scientific progress by the employment of ignorant facetiousness.

An illustration of the editorial preaching of reckless misinformation regarding the development of typhoid germs in horses and the consequent alleged danger of eating horse meat—a statement emanating from Hearst papers under the editorship of Arthur Brisbane—was referred to recently in The Journal.[1] Under the caption "Futilities of Contemporary Science," a newspaper of no less dignity than the New York *Times*[2] attempts to exploit in semijocular vein the press dispatches regarding investigations of Hindhede of Copenhagen on restricted diets. This student of nutrition, who has long advocated economy in diet and particularly in the use of animal protein, has lately shown that adults could live without apparent detriment for a period of more than one and one-half years on a ration of bread, potato, vegetables and fruits without added fats. Such experiments, among many others that might be cited, help to rob the vision of meatless days and beefless weeks of the terror which it inspires in the breasts of the uninitiated. Man's health and strength are not dependent on the assumed superior virtues of animal flesh as a dietary constituent.

Every physician with scientific training is aware of the uncertainty existing with respect to the precise rôle of fat in the economy. Aside from the fact that fats yield more than twice as much energy per unit of substance as other foodstuffs, the demonstration that animal fats often act as carriers of vitamins essential to physiologic welfare has begun to raise new questions as to the indispensability of this group of nutrients. In the current discussions of war edema, the xerophthalmia of babies fed on fat-free milk and cereals, and other diseases of dietary deficiency origin, the possible need of fats as such or what they may include has become prominent.[3] It has been repeatedly reported by competent observers that the low fat ration in Germany, at least in the earlier period of the war, was regarded as one of the most severe deprivations of the population.

Surely, then, reputable investigations of nutrition successfully accomplished in spite of a dearth of fats are likely to command attention in the scientific world. The presumable potency of potato protein, the possible occurrence of adequate vitamins in the green vegetables —these and other timely topics are involved in Hindhede's announcement in his Danish report, of which a brief summary has been transmitted by cable. Yet the New York *Times*, evidently ignorant of the real significance of its "news," indulges in the following supposedly humorous animadversion:

> How painful, then, it is to read that a distinguished Scandinavian, Dr. Hindhede, has established the fact that man can get fat without eating fats! Those misguided individuals who want to know how to get fat are few, and material for the gratification of their strange desire is ready to the hand of most of them. That men could continue to live, work, think, and maintain at least a minimum of health with very little fat in their diet was already established, for in vast regions of half-fed Europe they have been doing that for months and years past; no Scandinavian researches were needed to establish that.
>
> If Dr. Hindhede and his colleagues among neutral scientists wish to devise something that will bring real solace to the world after the war is over, let them devise some diet on which anybody can get thin. The mere verification of suspicion that whatever you eat or do not eat you will still have to let out your belt, may prevent some needlessly painful dietetic penances, but it does nothing to alleviate the agonies of the adipose.

Where ignorance is bliss 'tis folly to be wise. But it is worse than folly to allow ignorance to concoct belittling facetiousness at the expense of the efforts of modern science—particularly in a day when science admittedly needs to be encouraged to its utmost.

ARE ANTITOXINS PROTEIN IN NATURE?

Ehrlich's hypothesis that an antitoxin consists of "cell receptors" that have been produced in excess and secreted by body cells into the blood has doubtless been a helpful conception stimulating pathologists or immunologists—as the specialists are now designated—in the investigation of immune serums. To the chemically trained mind, however, it falls far short of suggesting something definite or tangible and in any way comparable with the more familiar compounds that are known to play some part in biologic processes. The fact that the neutralization or detoxication of toxin with antitoxin can be carried out quantitatively in a beaker as well as in the body is an indication that specific substances are involved in such reactions. According to Arrhenius, the interaction of toxin and antitoxin is accompanied by a liberation of heat much as is the action between strong acids and bases.[1] The concurrence of opinion further opposes the idea that antitoxins are in the nature of chemical ferments or enzymes.

Although the actual chemical nature of antitoxins is unknown, the antitoxic properties of such immune serums as are employed in combating diphtheria are closely associated with the globulin fraction obtainable from this part of the blood by current methods of protein separation and purification. There is some evidence, derived from data regarding their comparative diffusibility, to indicate that antitoxin molecules are much larger than the toxin molecule;[2] and this fact, along with the deportment of antitoxin in the attempts to concentrate it from serums, is often adduced in favor of its protein nature. Although it is possible to retain all of the immunity units along with only a part of the protein, no one has succeeded in separating the antitoxins from their associated proteins.

At the Bureau of Animal Industry in Washington, Berg and Kelser[3] have attempted anew to secure a protein-free antitoxin preparation on the one hand, and on the other to determine whether antitoxin can be destroyed by procedures that leave the protein intact. Success in either direction would indicate that antitoxin may be of nonprotein nature. According to the method proposed by the government pathologic chemists, if an antitoxin—tetanus antitoxin, for example—is a substance of nonprotein nature, it should be possible to prepare artificial digestion mixtures containing the antitoxin serum or antitoxin derived therefrom, in such fashion that the protein would undergo digestion without loss of antitoxin. Appropriate chemical measurements would indicate the extent of proteolysis, while inoculation experiments on guinea-pigs would indicate whether there was any loss of antitoxic units. If, on the other hand, the antitoxin is a protein and its power to neutralize immunologically the corresponding toxin is a function of the intact protein molecule, then the antitoxin would be destroyed in every case in which the protein had undergone cleavage, regardless of whether the cleavage was caused by a proteolytic enzyme or other chemical agent. Due regard must of course be had for the possible destruction of the toxin by the chemical agents used in the experiments.

The outcome of the experiments of Berg and Kelser has been to indicate that antitoxin destruction may take place with or without cleavage of protein. Dilute acid or alkali may destroy the antitoxin within a period in which significant chemical changes in the accompanying protein cannot be detected by the tests adopted. The authors interpret their results as indicating that tetanus antitoxin is a substance of nonprotein nature. But, they add, the stability of the antitoxin is so dependent on that of the protein to which it is attached that whenever the protein molecule is split, the antitoxin splits with it. It would be folly, however, to regard these demonstrations as conclusive so long as a protein-free antitoxin is not obtained. Proteins are susceptible to molecular rearrangement by the action of an alkali, for example, without having their gross composition altered thereby. The antigenic properties of proteins can be entirely altered in this way, as Ten Broeck[4] found in the case of the racemized protein of Dakin, which still seems to possess all of the amino-acids present in the original active substance.

THE UROBILIN PROBLEM

It is nearly half a century since urobilin was described by Jaffe. Little attention was paid to this substance from a clinical standpoint until its relation to the decomposition of bile pigment by bacterial action in the alimentary canal was made prominent by Friedrich Müller. The terms "urobilin" and "urobilinogen" are applied to a group of derivatives of bile or blood pigment for which methods of estimation, crude though they may appear to careful analysts, have been devised and widely applied to the examination of urine and feces by a considerable number of clinicians and in a great diversity of cases. Like many novelties in clinical chemistry—we may cite the indican test and Ehrlich's diazoreaction—the test for urobilin has attained a considerable popularity and has been the subject of generalizations that might appear highly significant and diagnostic to the uncritical reviewer. It seems worth while, therefore, to point out at this time that there are unquestionably obstacles to the ready acceptance of some of the current hypotheses.

[1] Arrhenius, S. A.: Quantitative Laws in Biological Chemistry, 1915.

[2] The literature on this topic is reviewed by Wells, H. G.: Chemical Pathology, Ed. 3, Philadelphia, 1918, p. 180.

[3] Berg, W. N., and Kelser, R. A.: The Destruction of Tetanus Antitoxin by Chemical Agents. Proc. Nat. Acad. Sc., 1918, 4, 174.

[4] Ten Broeck: Jour. Biol. Chem., 1914, 17, 369.

The recent theory that is perhaps the most prominent has been thus summarized by Robertson:[1] Urobilin is a decomposition product of bile, formed chiefly in the intestine by the action of putrefactive bacteria on the bile pigments. The quantity of urobilin in the feces does not represent the total amount of bile excreted into the intestine, for part of the urobilin is reabsorbed in the form of urobilinogen. Yet there seems to be a fairly constant relationship between the two, and the urobilin output may be taken as a rough measure of bile excretion. Since the amount of bile formed is, with a normal liver, directly dependent on the quantity of blood pigment brought to it, the variations in urobilin excretion may therefore be considered to indicate corresponding fluctuations in the amount of blood being destroyed. Robertson observed, in his clinical studies at the Massachusetts General Hospital, that those patients in whom the evidence of blood destruction was most marked gave the highest urobilin estimations. There was no case with a normal urobilin output which showed any evidence of abnormal hemolytic activity. Accordingly it seemed fair to conclude, first, that the quantity of urobilin in the stool may be taken as an approximate measure of the degree of hemolysis occurring in the body; and secondly, that such estimation is of very definite clinical value in the diagnosis of conditions questionably hemolytic in character, particularly in anemias that are of uncertain type.

These conclusions were in harmony with the views of Wilbur and Addis[2] of Leland Stanford Junior University, who have devoted much attention to the clinical significance of urobilin. They even state that by means of urobilin estimations in the stools, those forms of anemia associated with an increased blood destruction may be differentiated. They intimate that it is probably in this field that the most valuable diagnostic results will be obtained; and they point out the striking contrast which was found between the very large total urobilin elimination in pernicious anemia as compared with the small amount observed in secondary anemias following hemorrhage or carcinoma.

At the Mayo Clinic, Giffin, Sanford and Szlapka[3] have altered the technic by making observations on contents of the duodenum collected by means of an Einhorn tube rather than on stool extracts. As a result they report low values in secondary anemias, but high figures in cases of hemolytic jaundice and of pernicious anemia—the classic instances. The Rochester clinicians do not attempt any far reaching deductions, however, as to the interpretation of their findings.

What is to become of the enterogenous hypothesis of urobilin formation in the light of such clinical observations? Must it be abandoned? There is evidence that the urobilin substances may make their appearance in the urine independently of any presumable putrefactive origin in the bowel. Shall we then relate urobilin to some antecedent reaction associated with bile pigment formation, for example, to the failure of a proper bile pigment synthesis or to a disintegration of bilirubin in the liver or elsewhere? In this event it becomes necessary—if the original contentions of an interrelation between blood pigment destruction and urobilin formations are maintained—to postulate a direct relationship between hemoglobin and bile pigments. Such a hypothesis has found a serious obstacle in the researches of Whipple and Hooper[4] of the Hooper Foundation at the University of California. Their conclusions, termed "iconoclastic" by one recent writer[3] on urobilin, indicate that bile pigment production is influenced by dietary factors quite as well as by the blood factors. Thus, although the introduction of free hemoglobin into the circulation may be followed by an increased output of bile pigment, this is not an invariable and uniform response. In other words, the disintegration of blood pigment may not be the decisive factor in the production of bile pigments or their derivatives. It may turn out that urobilin is the expression of some impaired organ function as well as of blood destruction. Amid the uncertainty and confusion that have arisen, the clinician may well hesitate to take a decisive attitude toward the pigment problems.

SEED OILS AS NUTRIENTS

When we were warned, early in the war, that an impending shortage of fats—a deficit due to lack of tonnage and the extensive use of fats in the manufacture of munitions, as well as to decreased animal production—called for intelligent conservation of these foodstuffs, there was some uneasiness as to the outcome. It had early been heard as a prominent complaint against war time diets in Germany, in which the fats were said to be very low, that they do not "stay by" and consequently they put the consumer in the position of a dietetically unsatisfied individual. With a possible decrease in the procurability of butter, lard, suet and tallow impending, the vision of a perennially hungry public began to worry the food experts. But necessity is the mother of invention; consequently new sources of fats have come to notice and hitherto little used fats have gained a novel prominence. There are many wholesome and relatively inexpensive vegetable oils on the market which might be used more freely than they now are. Moreover, the U. S. Food Administration[1] assures us that the production of vegetable oils can be more easily and quickly increased in an emergency than the production of the animal fats.

The physiologist insists on something more than attractive appearance and palatability as a guarantee of nutrient virtues in newly proposed foods. He insists nowadays on the rigorous test of digestibility, etc., which can be furnished only by actual feeding experiments. Hence the government, through the agency of its Office of Home Economics, has sought information of this sort regarding the edible fats. In addition to the edible animal fats, all of which are proverbially digested well when eaten in amounts not in excess of those consumed in the ordinary dietary, some of the better known vegetable fats, including olive, cottonseed, coconut, peanut and sesame oils, as well as those expressed from common nuts, have passed the test.[2] The latest contribution[3] to the possibilities of fat for food vouches for the excellent utilization of corn oil, a refined by-product of the manufacture of corn starch, which has been used quite extensively in the preparation of lard substitutes and is now becoming quite a common household product; soy bean oil, long a fuel in the Orient and now giving promise of possible usefulness as a food; sunflower seed oil, which the American Indians were wont to use for food purposes and which the human subjects in the government tests consumed in excess of 90 gm. daily without objection; Japanese mustard-seed oil, a by-product of the manufacture of mustard for condimental purposes; rape-seed oil, already familiar to inhabitants of Europe and India; and even charlock oil, the product of a weed seed (wild mustard).

If we can accept substitutive cereals, why not substitutive fats? It must not be overlooked, of course, that some animal fats, notably milk fats, contain little known but very important substances — vitamins — without which the body cannot grow or recover from injury as it should. As these are not found in all vegetable oils, we must not fail to provide children and invalids with some animal fats, preferably perhaps from milk. The fact that some fats are solid and some oily does not affect their comparative wholesomeness. It merely gives us the problem of using them in new ways when once their physiologic availability has been suitably guaranteed.

Current Comment

OUR ANIMAL HERDS

The drought of this summer in parts of the Allied countries and in our own Southwest and in some Western states forces on the world's attention the great dependence of the human race on its animal herds. The war has led to such depletion in the animal stocks of European countries that they can be saved only from the outside and are looking particularly to us for help. We should remember that the little cans of condensed milk have become almost sacred symbols of our aid to hundreds of thousands of Belgian and French mothers. Since under war conditions the maternal nursing period is only from six weeks to three months, the continued development of all the peoples directly hit by the war depends on their dairy herds—now sadly depleted by slaughtering for food and by German thieving. The embargo on feed grains to neutral countries, such as Holland, has forced the slaughtering of hundreds of thousands of cows. It takes at least three years for any considerable herd increase in milch animals, so at the best the problem will be a most serious one. A scarcity of the world's food supply for the coming year brings out an interesting contrast to that of the years 1917-1918, since now the Allied countries' shortage, as well as our own, is in fodder and feed grains rather than in bread grains. The effect of this on our own country is hard to foresee.

THE EPIDEMIC OF INFLUENZA

The epidemic of influenza now sweeping over the country—a part of the pandemic now covering the world — reported in this country first from seaports and naval stations, and later from many cities, including at least twenty-five Army camps, with the craze for weird nomenclature accompanying war conditions, has been labeled "Spanish influenza." This, however, should not cause any greater importance to be attached to it, nor arouse any greater fear, than would influenza without the new name. This epidemic is of course modified as to its epidemiology by the fact that large numbers of the most healthful portion of our population have been segregated in military and naval camps. The condition presumably started in Spain and spread throughout the various armies. It has already practically disappeared from the Allied troops. A typical epidemic as it existed abroad is described in the paper by Hewlett and Alberty in this issue of The Journal; a typical epidemic at a naval station is described also in this issue by Lieutenant Keegan. It is needless and too early to discuss here the exact identity of the infectious agent. Few physicians will attempt to treat the condition with any special reference to its bacteriologic cause. The course of the disease is similar to the condition which has always been called influenza, except that it seems in some cases more severe, that it shows an extraordinary degree of contagiousness and that it is complicated or followed, in perhaps as many as 5 per cent. of cases, by a massive and rather fatal bronchopneumonia. In its great prevalence it recalls the epizootic of earlier years. In the epidemic at Chelsea, Mass., this pneumonia was found to be caused by the influenza bacillus, which was recovered from 82.6 per cent. of the lungs at necropsy, and in 31.6 in pure culture, frequently mixed, however, with pneumococcus or streptococcus infections. This pneumonia was fatal in 33⅓ per cent. of the persons attacked by it. Early reports of the epidemic at the Great Lakes Naval Training Station indicate a similar incidence of pneumonia and mortality. Medical authorities of the Army, the Navy and the Public Health Service are thoroughly alive to the condition, and are taking active measures to control it. These measures are based on our knowledge that the disease is transmitted from person to person by direct contact, or indirect contact through droplet infection, and that it is therefore to be controlled by isolation and prevention of the transmission of these discharges. Because of the tendency to the development of the secondary bronchopneumonia, patients should be treated in well-ventilated, warm rooms with special consideration for the possibility of this serious complication.

"UNCLE SAM, M.D."

Under this title Samuel Hopkins Adams writes in *Collier's* for September 21. It is an article that every physician should read. Mr. Adams says: "The vast and complex job of making over our peace doctors into war doctors is the nearest thing to 100 per cent. achievement that the government has yet performed in this war"; and his article tells the story of this job and the way it is being done. Mr. Adams is not writing from hearsay; he went to one of the medical officers' training camps, and in order to go through the routine, as he puts it, "became part and parcel of a decidedly active, not to say overcrowded life." The company to which he was assigned was the "crack company of the best battalion"; the company said so! Mr. Adams thus sums up his impressions of the camp: "If I had to select the one quality which chiefly characterizes doc in uniform, I think I should name gameness. Fuse with his determination and enthusiasm a certain healthy humility, born of the necessity of learning things from the bottom up, a prevailing readiness to help the man a little newer than oneself, and a complete sense of democracy, and you get an esprit de corps such as one would not believe possible in an organization so new and so constantly renewing."

THE MILK PROBLEM

The most insoluble of all food problems are those associated with dairying. Local conditions are widely at variance as to the expense of production and the increase in milk production. Advances in the price of milk strike at our children's welfare and encounter greater opposition than advances in the price of any other commodity. The successful efforts of health officers and of physicians to improve the quality and increase the safety of milk have necessarily raised the cost. Dependable milk and butter are absolutely vital to child welfare. With the short supply of fodder in many places, the cutting off of brewers' grains, the shortage of labor and the many difficulties surrounding milk distribution, public interest in maintaining the dairy herds must be kept up. Only by so doing can we care for the present emergency and keep intact the large herd needed for the replenishment of Europe. The medical profession has for years been in the forefront in the protection of the public on the milk question, and its influence must be felt even more now in every community, in order that we may be able to have a wide margin of safety in the size of our animal herd. A sympathetic survey of the question with wide dissemination of the facts so obtained would be a worthy service that far-seeing citizens can render in every community.

ADVERTISING

This, from the opening paragraph of a heart-to-heart letter of Swoboda—the gentleman who will "guarantee to give you perpetual youth"—to a prospective sucker:

> You would never forgive me, and I could never forgive myself, nor could the creative forces of the Universe forgive us, if I failed to bring you to the point of evolutionizing, consciously, progressively, and intensively.

As an advertising blurb, this ranks high. Although possibly the fourth paragraph from the same letter is almost as good:

> Through Conscious Evolution, I convert weakness into strength, illness into health, fear into confidence, timidity into courage, worry into optimism, a negative personality into a positive personality, and old age into youth.

And the production of super-men no longer is to be confined to the Central Empires, for:

> Conscious Evolution has made possible for everyone the possession of super-health, super-vitality, super-courage, super-aggressiveness, super-mental. power, and super every power.

And this is the sort of stuff which staid and respectable publications are willing to advertise, and even, if necessary, editorially defend. Evolution, we are told, has taken a million years to make a man out of a monkey; modern advertising reverses the process in a day.

Dental Dressers.—To provide for continued and systematic dental attention to schoolchildren without prohibitory expense to the rate payers, officials in the Derbyshire district of England, according to the *Medical Officer*, Aug. 10, 1918, at the suggestion of the dental officer of the schools, put into practice the training of dental dressers, young women, who, after six months or a year of training were found competent as dental hygienists and were able to detect irregularities of the teeth, detect caries by probe and mirror, chart defects correctly, do simple dressings, select septic temporary teeth for extraction, scale well, drill and excavate caries and make fillings where the pulp cavity was not reached, and extract temporary teeth. The 80,000 schoolchildren of the district would have necessitated the employment of ten full time dentists at an expense of 10,000 pounds, while by the expedient of employing dental dressers the number of full time dentists was reduced to three, each having under him three trained dental dressers at a total expense of 3,000 pounds.

Medical Mobilization and the War

Rank of Medical Aides to Governors

As a recognition of the importance of their work, medical aides to governors have been given the rank of captain in all states having a population of less than a million and a half, and of major in states having a larger population than a million and a half.

Red Cross Offers Mourning Emblems

The War Council of the American Red Cross announces that that organization will provide mourning brassards free to the parents or widows of men who have died in the service, and will furnish the same at cost to other members of the family. The brassard is to be worn on the left sleeve, midway between the elbow and shoulder, is a band of black broadcloth or other material, 3 inches wide, on the surface of which the regulation military star is embroidered in gold thread.

Military Pathologic Museum

Major C. J. Herrick, M. C., has been detailed to the Army Medical Museum for the duty of receiving and disposing of pathologic specimens forwarded to the museum from military centers at home and abroad. Interesting specimens from civil life will be received also. Major Herrick will see to the preparation and preservation of these specimens and will determine what disposition will be made of them; some will be kept as permanent exhibits for the museum; others will be distributed for instruction purposes; and others, including duplicates, will no doubt be sent to swell similar collections elsewhere.

Medical Students and the Draft

The Provost Marshal-General has addressed the following telegram to the draft executives of all states:

"It has been brought to the attention of this office that many Local Boards are calling registrants for induction who had enlisted in the Enlisted Reserve Corps of the Medical Department under Section 151, Old Regulations, on mistaken assumption that under telegram Number B 2546 such enlistment held the registrant in Class V only until September 16.

"Registrants who enlisted in the Enlisted Reserve Corps of the Medical Department as aforesaid should be held in Class V and should not be confounded with registrants who enlisted for special training in camps and schools for a limited period expiring September 16, referred to in Telegram B 2546. Please communicate contents of this telegram to all Local Boards.

Crowder."

Red Cross Mission to Italy

The Italian Tuberculosis Unit of the American Red Cross, under the supervision of Col. Robert Perkins, Red Cross commissioner of Italy, will sail in a short time to conduct a health campaign with the particular objective of stamping out tuberculosis. The director of the unit is Dr. William Charles White of Pittsburgh, and associated with him are Dr. John H. Lowman, Cleveland, chief of the medical division; Louis I. Dublin, New York City, chief of the division of medical statistics; Dr. Richard A. Bolt, Cleveland, of the child welfare division; Dr. Erwin A. Peterson, Cleveland, chief of the division of medical inspection of public schools; Dr. Robert G. Paterson, Columbus, Ohio, chief of the division of education and organization; Miss Mary S. Gardner, chief of the division of public health nursing, and Lewis D. Dement, Framingham, Mass., executive manager.

Medical History of the War

Further steps toward writing the medical history of this war are being taken by the training of men to illustrate pictorially the medical and surgical pathology which will come under observation in the camps and hospitals both at home and overseas. A section of a dozen or more enlisted men under the command of a commissioned officer are on duty at the Army Medical Museum for special training in this branch of art. Among other features of the training is a thorough course in anatomy. Dr. D. S. Lamb, the veteran anatomist of the museum, has been engaged in teaching these men by didactic lectures and by demonstration of the wealth of material in the museum. Dr. W. F. R. Phillips, dean and professor of anatomy of the Medical College of South Carolina, has about completed a course in practical anatomy, guiding the men through the complete dissection of cadavers. Dr. Phillips is now about to leave for Charleston, S. C., to take up his duties at the medical school there.

Commissions Offered and Orders to Active Duty

Successful applicants for commission in the Medical Corps of the Army receive a letter from the Surgeon-General's Office informing them that they have been recommended for a commission; they are also notified that commissions are now awarded with orders to active duty immediately on acceptance. In due time—it may be a week, or three or four weeks—the applicant receives a telegram from the Adjutant-General's Office informing him that he has been awarded a commission; and ordering him to active duty at a definite post within ten days *after date of acceptance.* The acceptance is to be telegraphed to the Adjutant-General's Office and the action taken telegraphed to the Surgeon-General's Office. In some instances the brief time allotted works hardship on physicians whose affairs could not be adequately closed up in this time. It is advisable for the physician, on receipt of the letter from the Surgeon-General's Office, to begin to arrange his affairs, but not to close up anything finally. If, on receipt of the telegram from the Adjutant-General's Office, the officer finds that he requires more than the ten days of grace before departure, he should delay sending his telegram of acceptance to the Adjutant-General, but only so long as is absolutely necessary.

Information for Disqualified Draft Registrants

On the recommendation of the Surgeon-General of the Public Health Service, the Provost Marshal-General of the United States Army has arranged to distribute through the local draft boards, a circular of instructions prepared by the Public Health Service called "Information for Guidance and Assistance of Registrants Disqualified for Active Military Service Because of Physical Disabilities." In the instructions accompanying this document, the Surgeon-General points out that in the first draft about one third of the men examined were rejected for physical disability and there will doubtless be many among those examined in the new draft. The object of the circular is to give to the rejected men definite instructions as to the meaning of their disabilities and to appeal to them to correct the disability as far as possible. This will not only serve to reclaim many men for military service, but will lessen the burden of illness and disability among those engaged in essential industrial work. The circular contains specific information concerning the commoner causes of rejection or deferred classification such as defective eye sight, teeth, feet, underweight, overweight, hernia, etc. It is said that experience has shown that the proportion of persons with physical impairment is greater in persons between 30 and 40 than those between 20 and 30. This means, probably, that more disability will be found among those called by the new draft. Each registrant rejected will be given one of these circulars and in addition arrangements have been made by which specimens of the circular will be furnished to life insurance companies, fraternal organizations, labor unions, employers of labor and others who desire to reprint and make use of the circular. Requests for specimen copies should be made of the United States Public Health Service, Washington, D. C.

Promotions of Medical Officers Abroad

For some time considerable dissatisfaction existed among medical officers on duty in France because of the slowness of promotion, especially as compared with the rate of promotion of medical officers still in the United States. However, it has recently been announced that efforts are being made to accelerate promotion of reserve officers in France. July 29, recommendations were sent for the promotion of ninety-eight officers serving with the British Expeditionary Forces, and July 30, fifty-eight other officers were recommended for promotion. The *Stars and Stripes* for August 16 states that the policy governing the Medical Reserve Corps promotions recognizes that several factors should be considered in determining the rank of physicians coming into the Army in time of war: (1) age and length of professional experience; (2) length of active service, and (3) character of active service, taking into consideration whether or not it has been distinguished by unusual self-denial, gallantry, efficiency or hardships. Commanding officers and senior medical officers have been requested to accumulate data for determining these factors in the case of medical officers in line for promotion. It is understood, however, that officers under 31 years of age are not to be promoted except in special cases in which they have rendered unusual distinguished service and have been more than a year on active duty. All officers of the Medical Corps in Europe are to be placed on a roster according to age in each grade. The officer's age is to be determined by taking his actual age and adding four months for each month of service; thus, all lieutenants whose actual age is above 31 and who have completed one year's service will be eligible for recommendation to be promoted to captain. Taking the number of first lieutenants as a basis, the number of officers in the grades of captain and major are to be one lieutenant to 3.9 captains, to 1.7 major. It is understood also that the present recommendations for promotions to majorities shall concern only officers above the age of 40, and for promotion to captaincies only those lieutenants above the age of 35, except in special instances.

CORRECTION

The "Honor Roll" published in The Journal of June 1, 1918, should have contained the name of Lieut. H. L. HOLZBERG, M. C., U. S. Navy, attached to the Naval Training Station, San Francisco.

Microscopist GETHYN B. RUGAN, proceed *to Wilmington*, N. C., for duty in malarial investigations.

Medical News

(Physicians will confer a favor by sending for this department items of news of more or less general interest; such as relate to society activities, new hospitals, education, public health, etc.)

ARIZONA

Funds for Y. M. C. A.—Dr. S. E. Lynd, associate manager of the Phoenix, Y. M. C. A., convened a meeting at Flagstaff, September 12, for the purpose of raising the sum of $110,000—Arizona's quota for the support of the Y. M. C. A. abroad.

Cooperation in Health Matters.—To cooperate with the state health authorities in Arizona, Dr. Frederick T. Fahlen, St. Louis, has been appointed acting assistant surgeon of the United States Public Health Service for Arizona. Dr. Orville H. Brown, Phoenix, new state superintendent of public health who succeeded Dr. William O. Sweek, will cooperate with the United States Public Health Service representative in the expenditure of the appropriation for the control of venereal disease.

ARKANSAS

Physicians Meet.—The District Medical Association met at Portsmouth, September 15. Dr. Harry C. King, Fort Smith, conducted a surgical clinic at Sparks Memorial Hospital.

Free Clinic.—At Fort Smith a free clinic was opened, August 20, at which special attention is to be given to the welfare of children. Drs. James A. Foltz, Dred R. Dorente and Irving Sternberg are in charge.

Personal.—Dr. J. C. Geiger, formerly in charge of the United States Public Health Service work in Lonoke, has succeeded Captain Weldon in charge of the work of the Little Rock district. Dr. Geiger is an expert on sanitary conditions in rice field districts.——Dr. St. Cloud Cooper, Fort Smith, has resigned as a member of the state board of health.——Dr. William M. Burns, Argenta, has been appointed food administrator of North Little Rock.

CONNECTICUT

Personal.—Dr. Henry F. Moore, superintendent of health of Hartford, has obtained leave of absence to go to England to engage in war work.——Dr. Stewart W. Reid has been appointed police surgeon of Hartford.

DISTRICT OF COLUMBIA

Additional Personnel for Medical and Dental Inspection of Schools.—The new appropriation act for the District of Columbia considerably enlarges the force of medical and dental inspectors of public schools, increases the number of school nurses, and provides for four dental clinics in the public schools to be served by eight dental operators, who shall be half-time dentists at $700 per annum, and four prophylactic operators, who shall be graduate nurses trained in the inspection and cleaning of teeth; these last are to be full-time employees at $900 per annum. The number of medical inspectors is increased by one, and of dental inspectors by two, making the new numbers twelve and four, respectively. There are to be three additional school nurses—ten in all—at $1,000 per annum.

Escape of Leper.—John R. Early the leper and ex-soldier who has acquired nation-wide notoriety and occasioned interstate complications by his tendency to wanderlust, is once more at large, having escaped from his cottage by sawing through the iron bars which guarded the window of his room. That his liberty will be short lived may be assumed as the police authorities are vigorously on his trail. This escape from quarantine is the fourth excursion of the kind during four years. Once he found his way to the Pacific Coast, having been unrestricted in his movements for several months. When apprehended a lively dispute arose regarding the responsibility for his care; he was finally sent back to Washington, however, apparently on the ground that having been so indiscreet as to make the diagnosis the District authorities would have to bear the consequences.

Municipal Tuberculosis Dispensary Opened.—The past fortnight saw the inauguration of a new municipal social service work in the opening of the District of Columbia Tuberculosis Dispensary. The dispensary will be in charge of Dr. W. D. Tewksbury, who will have as assistants, Drs. Everett M. Ellison and Thomas Miller. A liberal appropriation was granted by Congress for this project and, while not yet complete, the equipment of the plant will be modern and ample. The roentgenologist in charge will be Dr. W. H. Merrill. The new dispensary will replace the outpatient work heretofore conducted under the auspices of the Association for the Prevention of Tuberculosis and will serve as the obviously necessary supplement to the excellent Municipal Tuberculosis Hospital. Later there will be established in the same building a social hygiene clinic, the chief of this service being Dr. Harry A. Fowler; Dr. William G. Young will be the second in command.

Personal.—Drs. A. L. Stavely and V. B. Jackson, both of whom have been ill and have undergone surgical operations of some magnitude, have recovered. Dr. Jackson is again actively at work, while Dr. Stavely has gone away for a vacation.——Dr. W. S. Bowen has recently recovered from an illness and has gone away for a much needed rest.——Dr. Harry S. Bernton, recently bacteriologist of the state board of health of Rhode Island, has been appointed chief of the bureau of preventive diseases and director of the bacteriologic and serologic laboratories of the health department of the District of Columbia. As chief of the contagious disease service, Dr. Bernton succeeds Dr. William C. Fowler, who became health officer following Dr. William C. Woodward's departure to Boston, and as director of the laboratories, he succeeds Dr. J. J. Kinyoun, who as major, M. R. C., is doing epidemiologic work for the Army.——Dr. E. W. Titus has been made deputy coroner, a post recently vacated by Dr. W. Browne Carr, now in the Army medical service.

ILLINOIS

Poliomyelitis.—A second case of infantile paralysis within a week was brought to the attention of health officers of Evanston, September 16.——One new case of poliomyelitis was reported, September 13, at DeKalb, making five cases under treatment at that time. Serum was being used in the treatment. The same date seven cases of scarlet fever were in quarantine.

Quarantine for Venereal Disease.—At Camp Grant, September 20, an order was issued by Col. H. C. Hagadorn, camp commander, that all men with venereal disease will be quarantined in special camps, two of which have been provided for colored men and one for white men. There are said to be between 1,000 and 1,200 men afflicted with venereal disease in the camp. Practically all these cases are in recently inducted men.

Personal.—Dr. Carl E. Black, Jacksonville, has been appointed a member of the Greek commission in charge of the surgical department and will sail soon.——Dr. Clarence H. Boswell, Rockford, has been reappointed county physician with the understanding that his contract is to be cancelled when he is called into military service.——Dr. Albert E. Campbell, Chicago, has been appointed district health officer of Springfield. He was formerly surgeon to the Illinois Central Railroad.

Illegal Practitioners Fined.—J. W. Schuppacher of Edwardsville, Madison County, was arrested by the Illinois Department of Registration and Education for practicing medicine without a license. The court assessed a fine against him of $100 and costs, amounting to $128.20. Joseph Zientek of 2610 Milwaukee Avenue, Chicago, was also arrested by the Illinois Department of Registration and Education for practicing medicine without a license and was fined $25 and costs by the municipal court of Chicago.

Influenza.—In addition to the large number of cases of influenza in the Great Lakes Training Station, there are many cases in the civil population in towns along the lake. September 17, 150 cases were reported at Lake Forest and 200 at Waukegan. The Army students at Fort Sheridan and all men in the Great Lakes Aviation Camp, in addition to the 50,000 men in the Naval Training Station, have been placed under quarantine. September 20, it is reported that the epidemic at the Great Lakes was on the wane, and it was expected that there would be a decrease in the number of cases daily.

To Treat Returned Tuberculous Soldiers.—A movement has been started at East St. Louis which has the support of the County Medical Society as well as the State Medical Society and the Illinois Tuberculosis Association through its president, Dr. George T. Palmer, Springfield, to provide appropriate and continuous care for soldiers returned from the front or from the army camps on account of tuberculosis. It is said that over 1,200 have been returned up to this time. Work in St. Clair County at East St. Louis is under the direction of Dr. Charles W. Lillie, county medical director. Similar work is to be undertaken in the other counties.

Correction of Remediable Defects in Registrants.—A plan has been worked out by the War Committee of the Illinois State Medical Society by which registrants who have been placed in Group 1, Class B, on account of remediable defects, may be provided gratuitous surgical and hospital aid in having their defects remedied. This plan, together with a list of competent and trustworthy physicians and surgeons, and a list of hospitals that will care for such registrants, has been presented to Major John M. Dodson, medical aide to the governor, and through these channels the adjutant-general of the state has been led to issue to the chairman of each local board the formal offer of the physicians and hospitals to provide such service to registrants with remediable defects, together with a list of the hospitals and surgeons in the territory most convenient to any particular registration district. Accompanying these lists, which will be added to from time to time, are blanks on which the postponed registrant is invited by the local board to have his defect remedied, giving him a list of physicians and surgeons in his neighborhood who have made the offer of gratuitous service, a blank on which the registrant accepts the offer and selects the surgeon and hospital, a blank to be furnished the registrant addressed to the surgeon selected and one to the hospital selected. The registrant is given to understand that he need not accept the services of any of the surgeons named, but may employ one of his own choice. It is also provided that hospitals which cannot accept registrants for free treatment shall notify the local board of such fact and give their minimum charge for taking care of the registrant, so that the local board may arrange for the payment of such charges through some organization seeking to aid the government. Due publicity is to be given in the neighborhood of the circumstance of the registrant being willing to have his defect remedied that he may enter the service, so that he may be given credit for his patriotism, and also to encourage others to have their physical defects remedied.

INDIANA

Anesthetists to Meet.—The fourth annual meeting of the Interstate Association of Anesthetists was held in Indianapolis, September 25 to 27, at the Claypool Hotel. Dr. E. H. Embley of Melbourne, Australia, and Dr. James Cotton of Toronto, Canada, attended the meeting.

Returned Home on Acount of Tuberculosis.—September 16, the Indiana Society for the Prevention of Tuberculosis received notice of the return of 161 Indiana boys who have been discharged from the Army on account of tuberculosis. This makes a total of 565 discharged from the Army on account of this disease.

Quarantine for Venereal Disease.—An ordinance recently passed by the Indianapolis City Council in the interest of the eradication of venereal disease became effective, September 2. All such cases must be reported and the afflicted person must obtain treatment from a licensed physician and undergo detention in his own home.

Scholarship Provided by Will.—The will of Dr. Nikodem G. Borisowicz, South Bend, provides for a scholarship for a Polish student with a high school education at the Polish National Alliance College at Cambridge Springs, Pa., for the acquisition of an education in a civil profession. A committee is named to administer the trust.

Indiana Physician Receives Military Cross.—Under date of August 19 a list of Army orders by Gen. Sir Herbert Plumer announces the award of the military cross to Lieut. Glenn D. Ransom, M. C., U. S. Army, attached to the 5th Battalion of the Cameron Highlanders. Lieutenant Ransom resided in Hamilton, Ind., before entering the service.

Influenza Survey.—Dr. John N. Hurty, secretary of the state board of health, has ordered a survey of the state to ascertain how prevalent is the influenza. He has sent inspectors of the state board to visit Indianapolis factories engaged in war production and has asked the county health officers of the different cities in the state to report to him.

Addition to Antituberculosis Camp.—Mr. John W. Boehne, ex-mayor of Evansville, has contributed money to erect a new addition to the Boehne Antituberculosis Camp, near Evansville. The addition will cost about $12,000 and will be used for the returned soldiers who are suffering from the white plague, twenty of these now being in Vanderburg County. The new addition will accommodate from forty to sixty soldiers.

County Tuberculosis Hospital.—It has been announced that a board of county commissioners has full power to establish a county tuberculosis hospital without first submitting the question to the voters of the county or without the board being petitioned to establish such a hospital. However, if a board should refuse to establish such a hospital, the citizens, by means of a petition signed by 200 freeholders and an election, can force it to do so if the majority of the voters are in favor of it.

For a Joint County Tuberculosis Sanatorium.—A campaign is being conducted by the Indiana Society for the Prevention of Tuberculosis to secure the vote of the electors at the November election for a tuberculosis sanatorium for four counties, Noble, DeKalb, Steuben and La Grange. At the Kendallville fair, a headquarter tent was maintained and the campaign carried on by means of lectures, literature and personal solicitation. Similar work is being carried on in other districts of the state. In Marion County a full-time teacher, hired for the purpose, will give regular instructions in measures to prevent tuberculosis in all public schools.

IOWA

State News.—At Vinton the main building of Tilford Academy has been sold to the city for a hospital for $50,000, which sum has been left by the will of Miss Virginia Gay to establish a hospital in her name.——At Fort Dodge, the *Eleanor Moore Hospital*, given by Hon. S. L. Moore, who kept up the yearly financial deficit, is about to be closed on account of the scarcity of physicians. Unless Mr. Moore can make some other arrangements, the hospital will be closed until after the war.——The sum of $24,000 has been alloted to Iowa, a part of the $1,000,000 federal apppropriation for the control of venereal disease. This expenditure will be under the supervision of the state board of health.——At Clinton, September 18, eight cases of infantile paralysis were under quarantine.

MAINE

State News.—The state department of health is now carrying on, in cooperation with the government authorities, important sanitary and disease prevention measures in the Portsmouth-Kittery Civil Sanitary District and Bath, in connection with the shipbuilding industry in which there are engaged several thousand workmen. Dr. Paul Treble of the U. S. P. H. S. has been placed in charge of the district on the recommendation of Dr. Leverett D. Bristol, state commissioner of health.——In the venereal disease campaign, Dr. Harry E. Hitchcock, formerly district health officer for the northern part of Maine, has been placed in charge.——According to the report of the state board of health during last month, 390 children were born in the state who had not been named at the time the reports were sent in. This omission makes the certificates worthless to the individual for establishing the date of his birth. During the time named there were 1,062 births. This shows that about one third were improperly reported.

MARYLAND

Infantile Paralysis.—An additional case of infantile paralysis occurred in southwest Baltimore, September 17, in a white baby 5 months old. Thirty cases have been reported in Baltimore since March 30.

Meetings.—The Baltimore County Medical Association held its monthly meeting at the base hospital at Camp Meade as the guests of Lieut.-Col. Lloyd A. Kefauver, Manila, P. I., and the medical officers, September 18. Following the medical meeting, supper was served at the camp.

Personal.—Major J. Albert Chatard, Baltimore, who, prior to his departure for Italy, was head of the medical service at the U. S. Army General Hospital No. 2 at Fort McHenry, Baltimore, has arrived overseas.——According to a cable dispatch, Capt. Harry W. Maxson of Baltimore, who was captured by the Germans last February, is now interned in the officers' camp at Rastatt, Baden.——Dr. Walter L. Denny of Baltimore has resigned as a member of the board of police surgeons to enter military service. Dr. Denny has been engaged in government medical work for the past year.——Dr. John D. Fiske, official physician to members of the crews of foreign vessels, who has been ill at Johns Hopkins Hospital, is now convalescent.——Dr. John M. T. Finney, surgeon in chief of the American Expeditionary Forces, on his recent visit to the United States laid plans before the president for the establishment of hospitals for the treatment of shell shock. The necessary funds have been provided and Dr. Finney has returned to France, where he has made a special study of shell-shock cases.

NEW YORK

Memorial Wing for Peekskill Hospital.—A fund is being raised to build a memorial wing to the Peekskill Hospital in memory of the seven volunteer firemen killed recently in the Fleischman Plant at Peekskill. Thus far $12,000 has been subscribed.

Medical Meeting Postponed.—A meeting of the Medical Association of Central New York, which was scheduled to take place October 17, has been abandoned on account of the absence of many members at the front. The next meeting will be held in 1919. Dr. John J. Buettner, Syracuse, is president, Dr. Robert Burns, Syracuse, secretary, and Dr. Thomas F. Laurie, Syracuse, treasurer.

New York City

Personal.—Dr. Abraham Jacobi's summer home at Lake George was destroyed by fire on the night of September 20. Dr. Jacobi, whose sleeping apartments were cut off from the rest of the building by the flames, had a narrow escape, but suffered from nothing more serious than shock and a few bruises. A valuable collection of historical antiques was destroyed.

New York Academy of Medicine.—The first meeting of the New York Academy of Medicine for the season 1918-1919 will be held, Thursday evening, October 3, at 9 o'clock. At that time Prof. Graham Lusk, one of the representatives at the recent meeting of the Interallied Scientific Food Commission abroad, will deliver the Wesley M. Carpenter lecture, his subject being "The Scientific Aspect of the Interallied Food Situation."

Raising Funds for Hospital.—The women physicians of the New York Infirmary for Women and Children have started a campaign to raise $200,000 for this institution. Dr. S. Josephine Baker is chairman of the campaign committee of 400 volunteer workers. Others active in the effort to reinstate this institution are Dr. Anna Howard Shaw, Dr. Alice E. Wakefield, Dr. Louis D. Ray and Dr. William Emmet Cuff, all of New York City.

More Women Doctors Sail for France.—The second unit of the American Women's Hospitals, which is to be added to the staff of the military hospital directed by Dr. Barbara Hunt, Bangor, Me., at present working with the Sixth Army Corps in cooperation with the American Committee for Devastated France, has sailed. The unit includes the following: Drs. Caroline M. Purnell, Philadelphia; Mary L. Evans, Middletown, Conn.; Charlotte Fairbanks, St. Johnsbury, Vt.; M. Ethel V. Fraser, Denver; Mary MacLachlan, Portland, Ore., and Ier Jay Manwaring, Norwich, Conn. Dr. Purnell is special commissioner for the American Women's Hospitals in France.

The Influenza Situation in New York.—According to a statement made by the health department, September 20, there were at that time about 450 cases of influenza in the greater city. Health Commissioner Copeland expresses the opinion that the disease is not getting away from the control of the health department, but is decreasing. Citizens who have contracted the disease are quarantined and the health department is prepared to compel patients who may be so situated as to be a menace to the community to go into hospitals. The bacteriologists of the department of health find Pfeiffer's bacillus in a large percentage of the cases, and, in addition, a minute organism, as yet unidentified. In order to better control the spread of influenza the health board at its regular meeting, September 17, placed pneumonia and influenza on the list of diseases that must be reported by all physicians.

Change in Administrative Methods in Health Department.—Certain changes in the administrative system of the New York Department of Health are to go into effect, October 1, having for their purpose the coordination of the work of the department and the granting of autonomy to the boroughs. The chief officer in each borough, known as the assistant sanitary superintendent, will become the head of that borough. There will be attached to each of the boroughs, as at the present time, a representative of each of the bureaus of the department requiring field representatives. All the employees in a given borough will be under the direction, supervision and control of the assistant sanitary superintendent, though it is understood that, except in cases of emergency, each employee assigned to a borough office for the work of a given bureau will not be taken from that particular work without orders from the commissioner's office. Questions of policy, exceptional conditions, and changes in personnel will be brought to the personal attention of the commissioner, who will make final decisions in cases of disagreement between the sanitary superintendent and the head of any borough. It has been the belief of those directly interested in the administration of health department work that in a city as large as Greater New York the borough office should have greater authority in the administration of local affairs, since in this way there could be personal contact with an actual knowledge of local conditions impossible under the centralized bureau system, and especially impossible under the triple headed district now in force. The change will overcome these objections. The more minute details of the new plan have not yet been made public.

OHIO

State Meeting Abandoned.—The meeting of the State Medical Association, which was to be held at Columbus, October 1-3, has been abandoned on account of war conditions and the demands on the medical profession.

PENNSYLVANIA

Urge Better Medical Care.—According to a preliminary report submitted to the state health insurance commission by its investigating staff, there is an average loss of 8,400,000 working days a year in Pennsylvania. It is also asserted that a large number of the serious illnesses appear to be due to the lack of medical care for minor ailments; that present facilities for medical care of employees are not satisfactory and that a study of a typical working class district in Kensington, Philadelphia, showed that more than half of the illnesses were those of wage earners and that each sick worker lost an average of thirty-nine days' time and almost $80 in wages. Recommendations for reducing this waste of industrial forces will be placed before the legislature next January.

Philadelphia

Influenza Made Reportable Disease.—September 21, the board of health made "Spanish" influenza a reportable disease in order to bring it under immediate control among the civilian population. All physicians are called on to report cases and to isolate every patient.

Gift to the Blind Fund.—The biggest individual subscription in the campaign to raise $150,000 for the Pennsylvania Working Home for Blind Men was announced, September 19. It was $10,000 and was given anonymously with the stipulation that an additional $90,000 be collected before the end of the campaign. Up to September 19, $61,000 had been collected.

Personal.—Dr. Cornelius T. McCarthy, now a first lieutenant in the United States Army Medical Corps attached to the British army, has been awarded the British military cross for the second time.——Dr. Samuel L. Baron has been made assistant school medical inspector, bureau of health, with a salary of $600.——Dr. Edwin S. Darby, who resigned from the dental department of the University of Pennsylvania a year ago, after more than thirty years of service, has returned to the institution at the request of the faculty and board of trustees.

Meeting of Babies' Welfare Association.—The Babies' Welfare Association held a meeting in the red room of the Bellevue-Stratford, Monday evening, September 23. The program follows: Neva R. Deardorff, Ph.D., American Red Cross, Washington, D. C.: "Birth Registration—A National Service"; Dorothy Reed Mendenhall, M.D., University of Wisconsin, representing the Federal Children's Bureau, Washington, D. C.: "The Reduction of Maternal Mortality"; John M. Baldy, M.D., president, Bureau of Medical Education and Licensure, Commonwealth of Pennsylvania: "The Demands of War-Time Obstetrics."

Medical College Reopens.—The Women's Medical College of Pennsylvania opened its sixty-ninth session, September 24. Dr. Martha Tracy, dean of the college, made the introductory remarks, and Dr. Eleanor C. Jones, professor of pediatrics, delivered the principal address. Announcement was made at the request of the government that a course for laboratory technicians had been added to the curriculum requiring seven months' study to complete it. Graduates in this course will be ranked as apprentice technicians in military hospitals. A high school education and a knowledge of chemistry and biology are necessary for matriculation. Seventy-five students were enrolled.

State Society Meeting.—The Medical Society of the State of Pennsylvania held its fifty-ninth session in Philadelphia at the Bellevue-Stratford Hotel, September 24 to 26, inclusive. General meetings were held Tuesday and Wednesday mornings and Thursday afternoon; specialty sessions, Tuesday and Wednesday afternoons and Thursday morning. Tuesday evening, a patriotic meeting was held in the ball room, and Wednesday evening, a reception for the president and officers of the society. Thursday evening, there were moving pictures of war activties and music. A meeting and supper of the secretaries of the component county society was held Tuesday evening at Kugler's. The commercial exhibit was open every day at the Bellevue-Stratford.

CANADA

Infantile Paralysis.—Infantile paralysis has broken out in Manitoba necessitating the closing of several schools, churches and moving picture theaters.

Spanish Influenza.—This new and stylish disease, if it is any other than our old friend the grip in a new dress, has appeared in various parts of Ontario, particulary in the Polish military camp at Niagara-on-the-Lake. Col. John W. S. McCullough, Toronto, the chief medical officer of health for Ontario, is sending an official circular to physicians throughout the province on the subject.

Personal.—Lieut.-Col. Ernest Raymond Selby,Calgary, Alta., a graduate in medicine, University of Toronto, 1910, who has seen prolonged service in the C. A. M. C., is reported wounded. Originally a captain with No. 2 Canadian Hospital, he was also attached to the First Casualty Clearing Station, and made M. O. 43d Battalion. He was mentioned in dispatches in June last.——Dr. James M. Johnston, Toronto, convicted last March of performing an illegal operation, has been sentenced for two years less one day at the Burwash Prison Farm, North Ontario. Dr. Johnston is 63 years of age, practiced in Toronto more than thirty years, and from real estate holdings in Toronto is possessed of an annual income of $20,000. His counsel is endeavoring to secure his pardon from the minister of justice. In the meantime he will be assigned to medical duties at the prison farm.

GENERAL

Prevention of Epidemic Influenza.—The rapid spread of the pandemic of influenza has led to the issuance by the Surgeon-General of the Public Health Service of a circular letter addressed to the medical officers in each of the United States quarantine stations with reference to the prevention of the introduction into the country on vessels of the disease referred to as "Spanish influenza." A short description of the disease is given and the methods for its control and treatment summarized in *Public Health Reports,* Sept. 13, 1918.

Board on Excreta Disposal.—The Surgeon-General of the Public Health Service has created a board to make a general study of the question of sewage and excreta disposal. This board consists of C. W. Stiles, U. S. P. H. S., chairman; Prof. E. B. Phelps, U. S. P. H. S.; L. L. Lumsden, U. S.

P. H. S.; Prof. G. C. Whipple, of Harvard; W. S. Rankin, of Raleigh, N. C.; Col. V. C. Vaughan, M. C., U. S. Army, of Ann Arbor, and Prof. E. O. Jordan, University of Chicago. It will undertake an extensive study of small sewage units, such as the isolated farmhouse, small hotels, etc. The headquarters will be at Wilmington, S. C., with extensive laboratories and experimental facilities.

Regulations for Allotment of Venereal Disease Funds.—*Public Health Reports*, Sept. 13, 1918, contains the regulations promulgated by the Secretary of the Treasury under which state boards or state departments of health receive an allotment of funds appropriated by an act of Congress, approved July 9, 1918. This act provides that a million dollars shall be distributed to the states for the use of their respective boards or departments of health in the prevention, control and treatment of venereal diseases. The fund is to be distributed to the states in the proportion which the population of each bears to the population of the continental United States, according to the last census, exclusive of Alaska and the Canal Zone. The regulations under which this fund is distributed are fully set forth. The assistance of the United States Public Health Service is made available to state organizations in this work.

Government Desires Platinum.—The chief of the Section of Medical Industry of the War Industries Board has issued an appeal to every one, including especially physicians and dentists, that on account of the scarcity of platinum and the great need of that metal for war purposes, each should go over his instruments and pick out every scrap of platinum that is not absolutely essential for his work. These scraps, however small, should reach government sources either through accredited representatives of the Red Cross, who will make a canvass for the purpose of collecting the platinum, or through any bank under the supervision of the Federal Reserve Board. Current prices will be paid for the metal. A warning is issued against giving scrap platinum to any one not authorized to represent the Red Cross. Platinum absolutely required for dental and surgical instruments and purposes will be released from time to time.

FOREIGN

Spanish Medical Party Visits French Fighting Front.—The Spanish government appropriated 30,000 pesetas to pay the expenses of a party sent to study on the spot the progress realized during the war in the treatment of wounds. The party is in charge of Dr. R. Molla, professor at the University of Madrid, and includes one licentiate from the medical department of each of the ten universities of Spain. The term "licentiate" is applied to those who have finished the curriculum but have not yet received the doctor's degree. The one representing the University of Valencia is a young woman.

Campaign Against Birth Control.—A national association has been organized in the Netherlands to combat the new malthusianism. Dr. H. Pinkhof, one of the editorial writers of the *Nederlandsch Tijdschrift*, is the president. A two-day congress is planned for December, to be held at Utrecht, and eight addresses are to be presented. The meeting is open to any one on payment of the free of 2.50 florins which entitles one to take part in the discussions, vote and receive a copy of the transactions. The four sittings are open also to others interested on payment of 1 florin. Dr. Pinkhof's address is Plantage Franschelaan 11, Bijkantoor Prins Hendrikkade, Amsterdam. The name of the association is the Vereeniging tot bestrijding van het Nieuw-Malthusianisme.

Hospital Fare in Germany.—The *Nederlandsch Tijdschrift* quotes an article in the *Deutsche medizinische Wochenschrift* by Professor Hoeflmayer of Munich in which he protests against the investigating committee which visits the hospitals and interrogates patients and others, seeking to discover among the inmates some who without being sick, feign illness and stay in the hospitals in order to get better food to eat. He comments on the injury done the sick by these searching examinations, and the lack of confidence in the hospital physicians which they display. "Even if one physician should connive at such practices," he says, "they could not be carried out without the participation of the other medical attendants. It would be better if the physician suspected were given a chance to defend his diagnosis before the board of control. This would facilitate matters for all hands, while a physician who might not be acting in good faith would not dare to risk conviction for perjury."

PARIS LETTER

Paris, Aug. 22, 1918.

Call for the Class of 1920

Legislation has been passed calling the class of 1920 (young men 18 years of age) to the colors. The minister of war has sent instructions to the prefects and the commanders in chief of the various regions that the most rigid medical examinations should be made in selecting men from this contingent. The medical examiners will be required to be as rigid in the examination of these young recruits as they are in the case of volunteers. They must not accept either for full or limited service men who are not physically sound, but they can postpone or temporarily exempt those who, without being the victims of a characteristic organic disturbance, nevertheless have a weak physique, with a general make-up and antecedents which predispose to tuberculosis. Only those men should be accepted who are sound physically, strong and robust, presenting physical attributes clearly adequate for service. A selection which sacrifices the quality of the recruits for numbers defeats the object sought. The development of diseases of all kinds and of epidemics is favored, besides needlessly exposing the men already in service. Hence, a most careful selection of new recruits is of first importance. In fact, it is an absolute necessity in the interests both of the army as well as of the country.

Personal

Dr. Pierre Delbet, clinical professor of surgery in the Medical Faculty of Paris, has been made commander in the Legion of Honor. The citation recalled his fame as a surgeon, known the world over, and that at the beginning of the war he placed his services at the disposition of the minister of war, without reservation. He has carried to a successful conclusion a number of missions which have had a most favorable influence on the treatment of the wounded. He is the originator of a new method of treating fractures which has yielded excellent results.

Dr. Hartmann, professor of clinical surgery, and Dr. Jean-Louis Faure, professeur agrégé, both of the Medical Faculty of Paris, have been named officers in the Legion of Honor.

Team Work Between the Surgeons at the Front and in the Interior

An important conference was held recently at the Ecole d'application de médecine et de pharmacie militaires du Val-de-Grâce under the presidency of Dr. Louis Mourier, undersecretary of state for the Service de Santé militaire. The purpose of the conference was to bring together the medical officers of armies and of army groups, the consulting surgeons of the armies engaged in the recent military operations, as well as the directors of the Service de Santé and the chief surgeons of the surgical sectors of the regions of the interior who have received the wounded directly from the front. It was desired to establish a *liaison* between the physicians and surgeons of the various armies, and permit an interchange of views between these and the physicians and surgeons of the interior, and to secure an expression of opinion as to the lessons that could be drawn, from the medical point of view, from the military operations carried out from March to June of this year. Questions of special importance discussed were: the placing and function of the advanced ambulance groups, the evacuability, transportation and apparatus needed for thigh fractures, and the indications and technic of suture of war wounds.

Honor to the American Red Cross

The American Red Cross has received a letter from General Gouraud, commander of the Fourth Army, in which he expresses his profound admiration of the excellent services rendered by the American canteens to the Fourth Army.

Legacy to the Hospice des Quinze-Vingts

An American, Mrs. William Taylor Moore, née Robinson, bequeathed to the "Hospital for the Three Hundred" (an asylum for the blind in Paris, founded by St. Louis) 100,000 francs for the care and instruction of French soldiers blinded by the war.

Spanish Mission to Paris

Dr. Molla, a member of the Medical Faculty of Madrid. and twelve other professors chosen from the faculties of various Spanish universities, have arrived in Paris. They will visit the principal medical and surgical centers, remaining in Paris for the entire month of August. The mission is charged to prepare a report on the progress made by French war surgery.

A New Type of Surgical Battle Formation

The Société française de secours aux blessés militaires has devised a new type of surgical ambulance which meets the needs arising during active military operations. This ambulance can be advanced and moved back quickly, being essentially different from those in use for some months. Furthermore, it enables the surgeons to render speedy, immediate and complete service to patients with extensive wounds of the thorax, abdomen or head. It consists of a number of large tents, one serving as a *salle de triage*, a second for local administration, another for preparing the wounded for operation, a fourth for radiography; an operating tent, connected with the sterilizer camion, which contains two autoclaves, and, finally, the hospitalization or ward tents. For transport, the whole outfit is carried in two camions or trucks and two trailers.

American Red Cross at the Belgian Front

The Belgian sovereigns received the delegation of the American Red Cross, headed by Major Perkins, European Red Cross commissioner, at the Belgian front. Major Perkins delivered to Queen Elizabeth the million offered by the American Red Cross to the Belgian Red Cross. The king thanked the delegation and expressed his appreciation of the assistance given by the United States.

LONDON LETTER

London, Aug. 27, 1918.

The Maternity and Child Welfare Act

The powers of local authorities to safeguard the health of mothers and young children have been enlarged by the maternity and child welfare act, the introduction of which was reported in a previous letter. The act enables local authorities "to make such arrangements as may be sanctioned by the Local Government Board for attending to the health of expectant mothers and nursing mothers and of children who have not attained the age of 5 years and are not being educated in schools recognized by the board of education." A local authority exercising powers under the act must appoint a maternity and child welfare committee which must include at least two women. One third of the committee may consist of persons specially qualified by training or experience in subjects relating to health and maternity who are not members of the local authority. The government grant is now available for the following additional services: hospital treatment for children up to 5 years of age; lying-in homes; home helps; the provision of food for expectant and nursing mothers and for children under 5 years of age; crèches and day nurseries; convalescent homes; homes for children of widowed and deserted mothers and for illegitimate children, and experimental work for the health of expectant and nursing mothers and of infants and children under 5 years of age. The Local Government Board seeks to secure that, so far as practicable, there shall be an efficient midwifery service throughout the country, and it looks to the municipal councils to organize the necessary arrangements. It is considered important that the status of midwives should be raised, and that competent trained women who devote themselves to this service should be adequately remunerated. They consider that a competent trained midwife, devoting her whole time to the work, should be able to secure an income of from $600 to $750 a year. A local authority may pay or guarantee the salary of a competent midwife, and suggestions for improving the midwifery service are invited. Each midwife should be seen by the supervising authority's inspector of midwives at least once a quarter, and on these visits general instruction and assistance should be given. A sufficient staff of competent inspectors—preferably qualified medical women—is therefore needed. Local authorities should arrange to pay the fees of physicians called in by midwives during the period of confinement, though in cases which are not necessitous the patients would no doubt repay the cost.

The board's standard of 500 births to each health visitor has been modified. Experience has shown that when the duties properly required of a health visitor are fully performed, a district with about 400 births a year is ordinarily as much as one worker can undertake. Other offices, such as that of tuberculosis nurse, school nurse and mental deficiency visitor, may be held with that of health visitor in certain cases, so as to give the officer a compact district and save traveling. The salary of a whole-time officer acting as health visitor, with or without these other posts, should as a rule be not less than $600 a year. In sparsely populated districts it may be convenient to appoint the district nurse-midwives of nursing associations as health visitors.

The home nursing services in respect of which the grant is now available are nursing needed for expectant mothers, maternity nursing, the nursing of puerperal fever, and the nursing of measles, whooping cough, epidemic diarrhea in young children, and ophthalmia neonatorum. The board notes with satisfaction the recent increase in the number of welfare centers in which mothers receive medical and hygienic advice on the care of their children, and say that, when practicable, there should be a center for each health visitor's district. Centers may be combined with school clinics, especially for ophthalmic and dental cases, and, subject to certain conditions, cots may be provided experimentally at centers on a small scale, but not for acute cases of illness.

The provision of further lying-in accommodation in the many areas where it is needed is encouraged by the board; and suitable "home helps" may be employed and paid by the authority, to look after a woman's home during her confinement. The home help should undertake the mother's ordinary domestic duties, including cleaning, cooking, washing, care of children, mending and marketing. She should not undertake any work which properly belongs to the sphere of the trained nurse or midwife, nor assist at a confinement unless a physician or a midwife is in attendance. Home helps should be specially trained at maternity centers and day nurseries, receiving practical instruction in plain and invalid cookery, food values and prices, laundry work, mending, infant care and hygiene.

Civics and Eugenics

The Summer School of Civics and Eugenics, which will last for nearly a fortnight, was opened at Oxford. The opening address was delivered by Prof. J. H. Muirhead of the Birmingham University, who said that civics meant an intelligent interest in the whole organization of civilized society, and especially the society to which they themselves belonged. This extension of citizenship from devotion to the parish or the neighborhood to the state raised a difficulty in regard to their emphasis on civic education at the present time. He would be asked, Was not this the mistake which Germany had been making, that she had put the state in front of education? The education of the citizen had begun, innocently enough, in the call to look beyond the narrow interests of individual or family egoism, but had it not ended in the creation of another or more terrible egoism—the egoism of the state; and had not the state just at the present time tried to impress the idea of citizenship as the leading mark of education? He accepted the warning of a German writer against making the state the supreme object of devotion. Were they making a mistake in emphasizing civic education or citizenship as the oriflamme of their new education? Would it not be better to take as their guiding motto the free personality of the individual, and, instead of emphasizing the education of the citizen into a word like civics, should they not emphasize the freedom of the individual soul, and, perhaps in some new science yet unnamed, the doctrine of freedom? Passing to eugenics, he said it meant more than a kind of "adult hygiene" concerned with inheritance, rather than habits. What he understood by eugenics was a way of looking at their civilization which emphasized the mental and physical inheritance as something which was the result of the long ages of the struggle of mankind on earth. It seemed to him a good omen and a step founded on true insight as to the nature of civics and eugenics that the two societies had united in this school. It was the first effort, he understood, at cooperation between them.

Engineers and Public Health

In the *Times* engineering supplement, attention is called to the necessity for collaboration between medicine and engineering in undertakings that affect the public health. It is pointed out that at present engineers often take on themselves work that ought to be done by geologists, chemists and bacteriologists, and this without due consultation with physicians, although they cannot be specialists in all these subjects. On the other hand, health officers are sometimes imperfectly acquainted with the possibilities of engineering in connection with the treatment of water and sewerage work generally, and without such knowledge they are obviously at a disadvantage in suggesting improvements. Proper collaboration between the engineer and specialists in the various branches of science concerned is therefore required, and would be the means not only of saving needless expenditure but of enhancing the efficiency of the works carried out.

Deaths

Zina Goodell Harrington, Mankato, Minn.; Albany (N. Y.) Medical College, 1857; aged 88; at one time a member of the American Medical Association; and president of the Minnesota Valley Medical Association; who in 1907 was presented with a loving cup by his co-workers in celebration of the completion of fifty years of practice; for several years president of Mankato State Bank; died at his home, September 10, from senile debility.

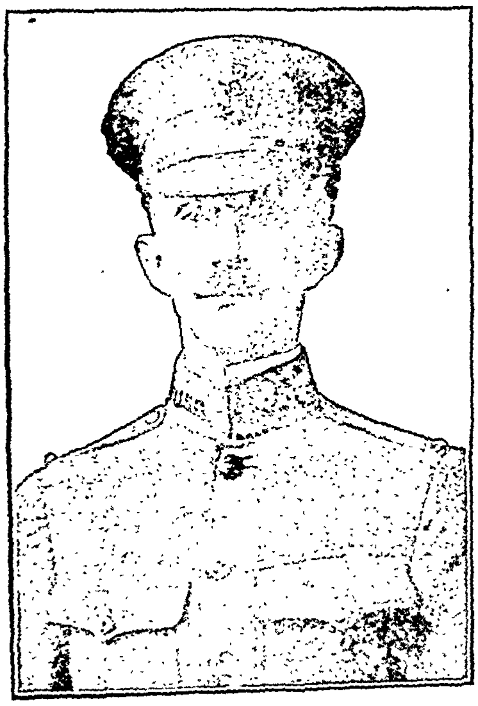
William Franklin Barclay, Pittsburg; Long Island College Hospital, Brooklyn, 1866; aged 76; a member and once vice president of the Mississippi Valley Medical Association; who discovered in 1893 and applied methods whereby he successfully combined gold with bromine, mercury, arsenic and other metals; died at his home, September 9.

Lieut. Samuel Brody Leiser, M. C., U. S. Army, Chicago; University of Illinois, Chicago, 1917; aged 26; a Fellow of the American Medical Association; who had been on duty at U. S. General Hospital No. 9, Lakewood, N. J., and was on leave in Chicago; died at the Presbyterian Hospital, September 16, from ulcerative colitis.

Walter C. Taylor, Springfield, Ohio; Starling Medical College, Columbus, Ohio, 1898; aged 52; a Fellow of the American Medical Association; secretary of the Clark County Medical Society in 1915, and president in 1918; died in the City Hospital, Springfield, Ohio, September 12, from pulmonary tuberculosis.

Benjamin Charles Guldin, Minersville, Pa.; University of Pennsylvania, Philadelphia, 1870; aged 69; at one time a member of the Medical Society of the State of Pennsylvania, and coroner of Schuylkill County; died at his home, September 1, from cerebral hemorrhage.

James E. Wylie, Little Rock, Ark. (license, Arkansas, 1903); aged 68; a practitioner for forty-one years; night desk sergeant at police headquarters, North Little Rock, for several months; died at the home of his daughter in Los Angeles, June 18, from nephritis.



Died in the Service
IN FRANCE
Capt. Hoddie W. Daniels, M. C., U. S. Army, 1872-1918
See The Journal, last week, p. 992

George Dexter Dulin, Las Animas, Colo.; College of Physicians and Surgeons, Keokuk, Iowa, 1891; Beaumont Medical College, St. Louis, 1892; aged 52; for two terms a member of the state legislature; died in St. Luke's Hospital, Denver, September 4, from pneumonia.

Lieut. Harold Greene Porter, Assistant Surgeon, U. S. N. R. F., Syracuse, N. Y.; University of Syracuse, N. Y., 1911; aged 25; a Fellow of the American Medical Association; on duty at the Naval Hospital, Chelsea, Mass.; died recently from influenza.

James Henry Briggs, Providence, R. I. (license, Rhode Island State Board of Health, years of practice, 1895); aged 64; a practitioner of Providence for twenty-five years; died in St. Joseph's Hospital in that city, September 8, six days after a surgical operation.

William H. Kinnier, Dubuque, Iowa; Albany (N. Y.) Medical College, 1870; aged 74; a member of the Iowa State Medical Society; died in Mercy Hospital, Dubuque, September 9, a short time after a surgical operation.

Felix Stanislaus Rynkiewicz, Shenandoah, Pa.; Jefferson Medical College, 1917; aged 27; until July an intern in the State Hospital for the Northern Anthracite Coal Region of Pennsylvania; died at his home, August 30.

John McIntyre, Butte, Mont.; University of Bishop's College, Montreal, Quebec, 1898; aged 52; a member of the Montana State Medical Association; died at his home, September 11, from disease of the kidney.

Edgar Chapman Gates, Providence, R. I.; New York University, New York City, 1882; aged 59; formerly surgeon in the United States Marine Hospital Service; died at his home, September 10, from heart disease.

Lieut. John Houston Steen, M. C., U. S. Army, Vaughan, Miss.; University of Nashville, Tenn., 1907; aged 37; a Fellow of the American Medical Association; is reported to have been killed in action, August 11.

Ferdinand Bernhard Hoermann, Watertown, Wis.; Homeopathic Medical College of Missouri, St. Louis, 1878; aged 74; died at St. Joseph's Hospital, Milwaukee, September 15, after a surgical operation.

James Barr, Sierra Madre, Calif.; Rush Medical College, 1868; Hahnemann Medical College, Chicago, 1880; aged 82; many years a practitioner of Algona, Iowa; died in Los Angeles, August 24.

Alvaro C. Durkee, Pontiac, Ill.; Rush Medical College, 1901; aged 47; a Fellow of the American Medical Association; died at his home, July 23, from uremia.

Died in the Service

Lieut. John Houston Steen, M. C., U. S. Army, 1881-1918

Robert Goodlove Harris, Sandersville, Ga.; Meharry Medical College, Nashville, Tenn., 1917; aged 33; died at his home, September 7, from tuberculosis.

Allen Schley Reynolds, Hancock, W. Va.; University of Maryland, Baltimore, 1880; aged 61; died at his home, September 9, from acute gastritis.

Lewis A. Shollenberger, Reading, Pa.; Hahnemann Medical College, Philadelphia, 1885; died in a sanatorium in New Jersey, September 2.

James Addison Ambrose, Dayton, Ohio; Medical College of Kansas City, Mo., 1882; aged 74; a veteran of the Civil War; died recently.

Nathaniel Gooch, Nashville, Tenn.; Vanderbilt University, Nashville, 1885; aged 78; a Confederate veteran; died at his home, September 7.

Marriages

Lieut. Floyd Walter Aplin, M. C., U. S. Army, Waukesha, Wis., on duty at Waco, Texas, to Miss Elsie Evans of Washington, D. C., at Waco, recently.

Alexander Stewart MacMillan, Boston, to Dr. Anne Leslie Hooper of Somerville, Mass., in Boston, September 5.

Mefford Runyon, Leak Island, N. Y., to Mrs. Katherine Flower Kip of South Orange, N. J., September 10.

James M. Palmer, Jr., Cumberland, Md., to Miss Ruth Maxwell of Morgantown, W. Va., September 7.

Theodore F. Thompson, Lakewood, N. J., to Miss Ella Anderson of Toms River, N. J., September 4.

Harry A. Pawling, Watertown, N. Y., to Miss E. Louise Sweet of Adams, N. Y., September 2.

Levi St. John Hely to Miss Sophie Wolters, *both of Oakland, Calif.,* September 4.

The Propaganda for Reform

In This Department Appear Reports of the Council on Pharmacy and Chemistry and of the Association Laboratory, Together with Other Matter Tending to Aid Intelligent Prescribing and to Oppose Medical Fraud on the Public and on the Profession

CARMINZYM

Report of the Council on Pharmacy and Chemistry

The Council has authorized publication of the following which explains why Carminzym was not accepted for New and Nonofficial Remedies. W. A. Puckner, Secretary.

Carminzym is a tablet sold by Fairchild Bros. and Foster, New York. Each tablet contains, according to claims made, approximately 32 mg. of an extract of pancreas, 50 mg. sodium bicarbonate, 172 mg. prepared chalk, 1.5 mg. powdered ipecac and "aromatics *q. s.*" Without considering other possible conflicts with its rules, the Council held the preparation inadmissable to New and Nonofficial Remedies for conflict with Rule 10 which holds that unscientific or useless articles are not acceptable products.

The Council holds that complex mixtures of remedial agents are, from every point of view, inimical to therapeutic progress and therefore to the public welfare. Such mixtures are especially objectionable because it is impossible accurately to determine the effects which follow the simultaneous administration of a number of drugs having dissimilar actions; because the practice of prescribing such mixtures tends to discourage careful consideration of the special needs of individual patients without which there can be no rational drug therapy. On the contrary, with the use of such mixtures therapeutic treatment becomes haphazard and mere guesswork.

The Council, appreciating that long established customs cannot be changed at once, has applied Rule 10 concerning the recognition of mixtures with the greatest leniency compatible with consistency. When there has been a reasonable doubt concerning the value of a mixture it has frequently directed that Rule 10 should not apply pending further clinical trial of such mixture. In no instance has subsequent experience shown that a strict interpretation of the rule would have worked hardship or injustice. The Council feels that there is no longer warrant for the admission of complex mixtures to New and Nonofficial Remedies or for the retention of any that have been admitted unless definite evidence of the therapeutic value of such combinations is available. In accordance with this decision several mixtures now described in New and Nonofficial Remedies will be omitted at the expiration of the three year period for which articles are accepted.

Reverting to the Carminzym tablet: When it is desired to obtain the effects of pancreatic extract by oral administration it must be administered with a view of preventing its destruction by the gastric fluid. With this end in view an antacid should be administered to decrease the acidity of the gastric juice. The amount of alkali may be supplied in the form of any of the official preparations, but the amount must be adjusted to the individual patient for the reason that no two successive patients are likely to have the same degree of gastric acidity.

Ipecac has a well defined though limited field of usefulness. When it is used, it should be given with a due regard to the amount needed by the patient and the frequency of the repetition of the dose. There is no reason to suppose that any two successive patients will require ipecac and extract of pancreas in a fixed proportion and with equal frequency. As a matter of fact, the amount of ipecac in Carminzym is so small that no definite therapeutic action can be assigned to it and its use in this combination is purely empirical.

In a word, the employment of mixtures of pancreatic extract, alkalis, ipecac and carminatives in fixed proportion leads to slipshod treatment and irrational therapeutics. Carminzym is an irrational mixture the use of which is detrimental to therapy.

The preceding report was sent to Fairchild Bros. and Foster for comment in accordance with the Council's usual procedure. The following reply was received:

> The long established custom of the use of mixtures of remedial agents rests upon considerations well known and generally accepted. This is equally true of combinations of drugs of similar and dissimilar properties. The drugs of these combinations, especially those of marked therapeutic action, are well known and used by themselves when indicated.
>
> In fact, dissimilarity of action is a cause of combination, an essential of synergism.
>
> Drugs classed as similar are by no means alike in action; laxatives, tonics, carminatives, diuretics are combined with distinct advantage, economy of dose, enhanced effect, potency not obtainable with the single drug.
>
> Your sweeping arbitrary conclusions that complex mixtures of remedial agents are from every point of view inimical to therapeutic progress is not, it seems to us, sustained by fact and experience. There is therapeutic progress in the considerate use and observation of combinations as well as in the use of a single drug. Indeed, in the production of a synthetic chemical substance as a therapeutic agent, the combination of potent and dissimilar elements is worked out to mitigate and correct an objectionable side effect, and promote desirable action.
>
> As for ourselves, at the very outset in our line of work we quite voluntarily declared our principles and our intentions as opposed to incompatible and therefore unstable or inert combinations of the enzymes; and against the "unnecessary multiplication of preparations" —see Fairchild's Hand-book of the Digestive Ferments.
>
> Is not this after all the crux of the whole matter—does a combination contain the ingredients stated, does it possess the demonstrable properties which are to be attributed to it in consequence of this composition; and if for a certain purpose, is it well designed therefor?
>
> Carminzym presents certain agents of well known properties, not in the least of incompatible or antagonistic action, but indeed especially suitable for the particular purpose designed; its efficacy not to be measured and judged by theory or opinion as to the efficiency of a certain dosage of a particular drug by itself. That the doses as contained are minimal and effective is distinctly advantageous.
>
> The alkaline carbonates are in Carminzym in stated quantities; the physician adjusts the dosage to the individual patient and with obvious evidence of the efficiency of the adjustment. As we understand it, the employment of alkaline carbonates is not based on purely chemic considerations—a definite known quantity of acid of the gastric juice is to be neutralized; the whole literature and practice dealing with the alkaline carbonates show them to be accredited with a much wider field of use and repute in gastro-intestinal disorders.
>
> The pancreatic extract in Carminzym is designed to be diffusible in the stomach, the tablet is preferable to be crushed in the mouth before swallowing, and we believe the pancreatic extract to be an effective constituent as administered in Carminzym.
>
> You comment as follows:
>
> > "Ipecac has a well defined though limited field of usefulness. When it is used it should be given with due regard to the amount needed by the patient and the frequency of the repetition of the dose."
>
> This in a sense may be said of any of the most useful drugs, but not in the least special degree does it apply to ipecac, which is, on the contrary, of quite characteristic, peculiar range of therapeutic properties, useful in varying combinations and in widely varying proportions and doses according to the purpose for which it is employed.
>
> Ipecac in well known official alkaline, carminative, laxative preparations occurs in the "average dose" in the varying qantities of 1/14, 1/10, 1/8 and 3/16 of a grain.
>
> The ipecac in combination with the other ingredients in Carminzym is designed for a tablet which shall carry a minimal quantity whilst capable of adequate remedial action, thus admitting of increase of dosage or repetition as occasion requires. This quantity of ipecac was not taken at random, but chosen after long trial and consideration.
>
> We believe that Carminzym possesses carminative properties in a superior degree and that, furthermore, in consequence of its composition it directly stimulates the gland secretions and thus exerts a beneficial action upon the whole digestive functions.
>
> Carminzym is for use as occasion requires, and this is to be especially noted. Thus it is not only of direct benefit, but helpful in promoting systematic therapeutic measures and regimen.
>
> The Council takes the ground that complex mixtures of remedial agents are so wrong that there is no longer warrant for their admission into New and Nonofficial Remedies; and that Carminzym is an irrational mixture.
>
> We hold that certain desirable therapeutic properties may rationally be attributable to Carminzym; and that these are manifested in practice.
>
> During the time since the description was sent and the receipt of the statement of the action of the Council, some ten months, Carminzym has proved of constantly increasing service.

The statement in the letter of Fairchild Bros. and Foster "The long established custom of the use of mixtures of remedial agents rests on considerations well known and generally accepted" might well be paraphrased to read: The one-time prevalent custom of using ill-considered combinations of remedial agents has been thoroughly discredited and is generally abandoned by progressive practitioners. Such arguments as that "laxatives, tonics, carminatives, diuretics are combined with distinct advantage" have led to the use of irrational mixtures such as the compound syrup of hypophosphites and the electuary of theriaca. The Council is confident that no one who has studied the causes and treatment of digestive disorders will find occasion to prescribe at one time all the ingredients stated to be contained in Carminzym, and certainly not in the fixed proportions present therein.

The comments in the Council's report concerning ipecac certainly does apply to all active therapeutic agents. Ipecac was mentioned in the report because the several constituents of Carminzym were under discussion and hence it was necessary to point out the futility of the small dosage of ipecac in this mixture.

The announcement that "Carminzym has proved of constantly increasing service" is not convincing. The Council does not know of a single clinical study of the action of Carminzym under conditions which would have afforded satisfactory evidence of its therapeutic value.

INFORMATION WANTED

One of the Five Thousand Letters of Inquiry Received by the Propaganda Department Annually

Probably few of The Journal readers realize the service that the Propaganda department gives the public and the medical profession as an information bureau on the subjects of the nostrum evil and quackery. Ten years ago letters from laymen were an unusual thing in The Journal's editorial office. If more than one letter a week, for instance, was received, it was a subject of comment by the staff. Today the Propaganda department alone, answers between four and five thousand letters annually, and more than half of these are from the general public. Among such letters it is inevitable that some should be oddities. One of this type is given below. It may be of interest not only to the readers of The Journal generally, but especially to psychiatrists:

Dear Sir:—I Have inquired so much about The International Health Resort, 42nd St. & Grand Blvd., Chicago, if it will do all it claims & been told you will give information. Please explain fully. My Doctor said I was on verge of Diabetes. Also tell me about the National Distributing Co., 4311-19 Lincoln Ave., Chicago. Will you give me Address of Alexander Moseley in Chicago, the street and number as He is among the testimonials in the *Evidences of Success* published By The resort, saying He visited all resorts in Europe and None Cured Him till He went to the International of Chicago. I want His Address so I can write Him and verify the statement. Can you recommend any of Bernarr MacFadden's Health Resorts as Best place to go for Kidney and Diabetes Troubles, or would you advise to have treatment By Correspondence from Him.

Please explain about the Bodi-Tone Co., 2100 North Avenue, your City. Please state very Best place to get urine examined from Time to Time. Is The Life Extension Institute, 25 West 45th St., New York City the Best place, or if you Know of Better please state.

Probably you can state some Institution in East Here that treats on same plan as International of Chicago.

I've been taking Chologestine, 2 teaspoonful after meals since June 7th & Has stopped Brick Dust in Chamber. Also take Bell Ans Tablets Before & after meals. Please state if Peptenzymes is good also Nuclinated Phosphates Tablets, Abbotts. Phillips Wheat Phos. (Acid).

Please give address of U. S. Public Health Service Department & can you tell me if Dr. F. L. Sweany, State St., your City is dead, if so when, and was he such a great doctor?

I would like to know if Lionel Strongfort, Terminal Bldg., 86 Park Place is thoroughly reliable & will do all He says. He claims to Be Best developed man in World & issues pamphlets giving Him recommendations from the professors in Europe. He gives course by Correspondence in Physical Culture. Would you commence with Him or take Lessons in person from instructor? which I want to take as it is Beneficial.

Or could you name some professor or institution Here in east which would Be Best for me to attend to get Best results. Can you give me standing of some of these Physical Culture Methods also Bernarr MacFadden's Course By Mail in "Brain & Body Building". He gives this Course in Conjunction with His Encyclopedia of Physical Culture. One is guide to the other. Or would you take Course personally & what benefit thereby? If any. Also about Walter LaRauss, 825 Broad St., Newark, N. Jersey. He claims Best System. Anthony Barker, 127 West 42nd St., New York City.

Do you think I would get all Benefit I would derive from all above mentioned in a German Turn Verein, Newark Turn Verein? The Paneliculator Co. of Cleveland, Ohio also sent testimonials Here from all over. Do you Know them? My Doctor, Says it is my liver & Pancreas & if I take Physical Culture with Medicines I'm told I will get results. But must get the right & proper Movements to accomplish results. So many Systems advertised in *Health & Physical Culture* Magazines. Please give me list of those fraudulent ones.

Can you give me standing of Advance Thought Publishing Co., 159 No. State St., your City & William Walker Atkinson who edits a Magazine on Clairvoyance. I think he is in that Pub. Co. at 159 No. State St. Also Yogi Pub. Society of your city. Thanking you very much for same in Advance & Truly yours,

F——— D———, New Jersey.

P. S.—Probably you can name very Best Physical Culture System that embraces all other System & get all in that System you recommend. I am interested also in Allied & Occult Sciences & Clairvoyance. Are there reliable Systems in Chicago at all? Do you recommend advertisements in *Nautilus*, New Thought Magazine?

Correspondence

THE USE OF SEWAGE AS FERTILIZER

To the Editor:—The present world crisis calls for the exertion of every effort to meet the unusual demands made on the people of our nation. Nowhere is this realized with greater force than in the matter of food production. On the one hand, the demands of our allies and our own demands call for a great increase in production. And on the other hand, the problems of transportation, labor and fertilizer are all working to make the task of increased production more difficult.

Of the latter, the matter of fertilizer has become an acute problem. In the first place, intensive farming calls for an increase in the amount of fertilizer used. And in the second place there is a serious shortage of fertilizer due to the fact that America has been dependent for so long a time on that imported from Germany. The supply from Germany being cut off, the shortage has become serious, and in some places has already affected the crops.

The subject of fertilizer shortage has been ably discussed by Frank Parker Stockbridge in the *World's Work* for May, 1918. His article showed how Germany annually dumped about 250,000 tons of potash in the United States at about $40 a ton. Today there is a call for 500,000 tons of the fertilizer. It cannot be bought for less than $300 a ton, and in limited quantities at that price. The magnitude of the industry and the need is thus shown.

Human feces and urine possess a high fertilizing value. It is a knowledge of this fact which has made intensive farming of the highest type a possibility in China, and which has made possible the feeding of many millions of people in comparatively limited areas.

Yet notwithstanding its high value as fertilizer, the use of sewage has been condemned because of the extremely high risk of spreading water and sewage borne diseases, typhoid, dysentery, cholera and intestinal parasites. For this reason, a recent order (The Journal, April 27, 1918, p. 1242) has prohibited the use of sewage as fertilizer in California except for grasses.

The danger from the use of sewage as fertilizer is very real. One of the triumphs of sanitation has been the lowering of the typhoid rate by a realization and the control of the relation between sewage and the water supply of a community. In China the use of human feces and urine has resulted in widespread infection with hookworm and *Ascaris lumbricoides*. And the only reason why devastating epidemics of cholera and dysentery have not depopulated whole provinces is that the Chinese are accustomed to use boiled tea instead of fresh water, which is never drunk as a beverage.

Shall, then, all this valuable material, so necessary and so useful as fertilizer keep on going to waste as it is at the present time? If necessary to preserve the health of the nation by preventing epidemics, the answer must be "Yes."

My purpose, however, is to present for consideration of the profession, and public health officers in particular, an outline of a plan by which it may be possible to use sewage as fertilizer, and with safety.

March 12, 1918, an experimental garden was planted for determining the value of the material from the second and third chambers of the septic tank, in use in the Kachek Hospital, as fertilizer. The purpose of the experiment (a report of which is to be published in the *China Medical Journal*) has been to work out a plan by which the Chinese may use human feces and urine as fertilizer with safety.

Three equal amounts of beans, millet and two other Chinese grains were planted in rows, one part to a row. One row was fertilized with material from the second chamber of the septic tank, one row was fertilized with material from the third chamber of the septic tank, and the third row—the control—was unfertilized. Thus there were three rows of beans, three of millet, etc. The results of the harvest are shown in the accompanying table. The value of the material from the septic tank as fertilizer has thus been demonstrated in a practical way.

FERTILIZING POWER OF MATERIAL FROM THE SEPTIC TANK

Foodstuff	First Row: Material from Second Chamber Used, Ounces	Second Row: Material from Third Chamber Used, Ounces	Third Row: Control; No Fertilizer Used, Ounces
Beans	42	29	12
Millet	5.0	2.9	1.7
Ku vae	84	66	49
Tiak kha	11.5	8.0	6.5

The action of the septic tank is well known, and needs no comment except to note that the material from the second and third tanks would contain no pathogenic bacteria, protozoa or ova, especially if treated with heat or chlorinated lime.

We have, then, a large quantity of fertilizer that can be made safe by means of the septic tank. That all the sewage of large towns and cities in America should go to waste in view of the present shortage of fertilizer, in view of the great demand for increased production of food, and in view of the fact that it can easily be made safe, is unpardonable. Steps should be taken at once to use this great asset. Not only will it solve the fertilizer problem during the war, but it will make America independent of outside sources of fertilizer after the war.

NATHANIEL BERCOVITZ, B.S., M.D.,
Kachek, Hainan, China.

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

SUGAR TREATMENT OF TUBERCULOSIS

To the Editor:—I read an article recently on "Sugar as a Cure for Tuberculosis." This article stated that Prof. Domenico Lo Monaco, director of the Biochemical Section of the Lincei Academy of Rome, is credited by the Italian scientific press with a discovery which will revolutionize the treatment of tuberculosis. Please inform me as to what form of saccharose is used, the strength of the solution, the number and frequency of injections, etc. I shall be grateful for an answer to the foregoing questions and for any other information you can give me concerning this treatment, as I have several cases of tuberculosis under my care.

L. C. J. NUNES, M.D., St. Martin, D. W. I.

ANSWER.—A brief note appeared in Queries and Minor Notes (THE JOURNAL, July 13, 1918, p. 142) concerning this treatment of Lo Monaco, merely stating that the subject was new and had thus far been referred to only in lay publications. The sugar treatment of tuberculosis is the result of researches since 1907 by Dr. Lo Monaco, who is professor of physiologic chemistry at the University of Rome. His researches have been concerned with the influence on the secretions of sugar parenterally introduced. He had previously considered the possibility of influencing the mammary and other secretions by subcutaneous injection of small amounts of sugar. He found that when persons with copious bronchial secretion were given subcutaneous injections of 4 or 5 gm. of saccharose, expectoration rapidly diminished and ceased completely in many cases. When the injections of the sugar solution were stopped, expectoration returned and disappeared again when the daily injections were resumed. A study of various cases indicated that a complete cessation of bronchial secretion occurred when there was no dilatation of the bronchi or when the cavities in the lungs were not large. When these were present the secretion decreased, but did not disappear completely. The sugar has an inhibiting action on the secretions through vasoconstriction, which the injection of strong solutions of sugar will produce. This vasoconstricting action affects the lymphatics and mucous glands. The strong solutions of saccharose also seem to have an antispasmodic action on the bronchi and bronchioles. This was demonstrated by La Grotteria, who utilized this method in the treatment of two cases of whooping cough. The technic utilized by Professor Lo Monaco consists of a daily intramuscular injection of 4 or 5 gm. of sugar or two injections of 2.5 gm. each. In persons emaciated by long sickness, in order not to cause pain, a few cubic centimeters of cocain solution are sometimes added to the solution. The solution is prepared by dissolving 5 gm. of saccharose in 5 c.c. of sterilized, distilled water.

In commenting on the treatment, the *Riforma medica* (1918, **34,** 354) says:

> The advantages of this new medication of the bronchi are truly notable, in addition to the fact that it avoids disturbing the gastro-intestinal functions, which is such a frequent drawback to the administration of drugs to act on the expectoration. The sugar treatment can be continued as long as desired, because it is harmless, to say nothing of the advantages of the sugar as a source for energy, developing a goodly number of calories in the intra-organic metabolism.
>
> In the tuberculous this method of treatment is of preeminent importance because even in the gravest cases it reduces the bronchial secretion and thus diminishes the cough and the annoying night sweats. On the side of prophylaxis, this new remedy, which, by the way, is entirely Italian in its inception, is destined to prove useful likewise, as if the expectoration is diminished there will not be so much sputum scattered about and hence there will not be so much chance of contagion from this vehicle of infection, the most dangerous and the most certain of all.

It is reported that the National Board of Health of Mexico is intending to organize free dispensaries to apply this treatment. One has already been opened in the capital, at the headquarters of the National Board of Health. It is in charge of Dr. M. Casas. It is also reported that this method is being tried in Italy in some of the sanatoriums for tuberculous soldiers and in France at the Bligny military tuberculosis sanatorium.

DIGESTIBILITY OF RAW WHITE OF EGG

To the Editor:—On the question in the subjoined paragraph; quoted from a recent publication, there seems to be a wide diversity of opinion among chemists and dietitians:

"Raw white of egg is much less digestible than cooked, and frequently causes diarrhea when taken regularly. Egg yolk, on the other hand, is easily digestible and is all utilized, whereas only 50 to 75 per cent. of raw white is assimilated."

May I have your opinion on this subject?

A. E. H., Illinois.

ANSWER.—This subject was discussed editorially in THE JOURNAL, Sept. 22, 1917, p. 1006. The supposed easy digestibility of raw white of egg was perhaps based on the observations of Dr. William Beaumont on Alexis St. Martin. Native egg white, he found, leaves the stomach very rapidly as compared with other foods. This observation does not take into account the subsequent fate of the substance after leaving the stomach. Bateman, and Mendel and Lewis, as well as other experimenters, have noted the poor utilization of egg white when fed to experimental animals, and its tendency to produce diarrheas. Bateman found that it was decidedly indigestible for dogs and when fed in any considerable quantities invariably caused diarrheas and sometimes vomiting. It was found also to be poorly utilized, and after tolerance was established to it in the animals it could be recovered unchanged from the feces, so that it was believed to be assimilated to the extent of not more than 85 per cent. It has been found to have a similar action in some persons, and its utilization in them has been found to be as low as 50 per cent. Reaching the large intestine in the unchanged state in considerable quantities, it may very well serve as a pabulum for putrefactive bacteria. This does not apply to the coagulated egg white cooked at a temperature of about 70 C., which removes the partial indigestibility and changes the egg white into a readily assimilable product. While perhaps raw egg may not be toxic in the correct sense of the word, yet aside from its indigestibility in contrast to the yolk of eggs, which seems t[illegible] and utilized, "the reputed relation of excess of egg white to renal damage, and the frequent hypersensitiveness to its proteins, offer additional reasons for debating the wisdom of the liberal use of raw eggs."

THE DETERIORATION OF ARGYROL SOLUTIONS, AND FLUIDEXTRACT OF ERGOT

To the Editor:—1. How rapidly do solutions of argyrol deteriorate? 2. Does fluidextract of ergot retain its strength indefinitely?

M.D., Binghamton, N. Y.

Answer.—1. The manufacturers of argyrol in their advertising matter repeatedly emphasize the necessity of using a "freshly prepared" solution. They state that office solutions "should be replaced by fresh solutions about every two weeks." Culver (*Jour. Lab. and Clin. Med.*, 1918, p. 487) found that the gonococcidal activity of a 2 per cent. solution exposed at room temperature to ordinary light for two months lost, for a five minute exposure, 75 per cent. of its efficiency. This loss of strength began as early as the third day, and it continued to lose in almost direct proportion to the age. He condemns the practice of having stock solutions, and states that the quantity prescribed for home use of a patient should not exceed a "few days'" supply. It would be better still, if possible, to have the solution prepared daily.

2. This subject has been the occasion for numerous painstaking investigations. A very complete bibliography is given by Eberhardt and Eldred in the *Journal of the American Pharmaceutical Association*, 1914, p. 42. The articles abstracted by these writers indicate that there is some difference of opinion among investigators. It is quite clear, however, that fluidextract of ergot kept under the ordinary conditions prevailing in the physician's office or in a drug store will lose its activity quite rapidly and may become inert within a year.

RANKS AND PAY OF MEDICAL OFFICERS AND OF ARMY CHAPLAINS

To the Editor:—1. Some time last spring you published a list of salaries paid to medical officers in the U. S. Army, their rank, etc. Please give me this information. 2. Can you inform me as to the rank of an Army chaplain and his pay?

L. L. H., Pennsylvania.

Answer.—1. The ranks given to medical officers and the annual pay received are as follows: lieutenant, $2,000; captain, $2,400; major, $3,000; lieutenant-colonel, $3,500; colonel, $4,000; brigadier-general, $6,000 and major-general $8,000. Commutation for quarters: lieutenant $432; captain, $576; major, $720; heat and light: approximately $80, $120 and $160, respectively.

2. A chaplain receives the rank of lieutenant, captain and major, in accordance with his age and qualifications. His salary is the same as that of other officers of similar rank, beginning with lieutenant.

REPORTING FOR DUTY—EQUIPMENT

To the Editor:—I was examined for a commission four weeks ago and so far have heard nothing from it. As I am rather above the average size, I shall have to have my clothes made to order, which requires about ten days. Some of my friends are ordered to report in ten days from the date of the notice, which gives insufficient time in which to become equipped. 1. Should I take the chance and order the uniform now before I have been notified that a commission has been awarded to me? 2. May a man report in civilian clothes? 3. Should the uniform be worn when making the trip to the place at which one is to report? 4. Should a service hat or cap be worn when reporting for duty? Please omit my name.

K. G. E.

Answer.—1. See item, "Medical Mobilization and the War: "Commissions Offered and Orders to Duty on Acceptance," this issue. 2. Yes; but preferably in a uniform, completely equipped. 3. Yes. 4. Either; preferably, the hat.

WHEN MEDICAL OFFICERS MAY WEAR THE UNIFORM

To the Editor:—Is it proper for a doctor to wear his uniform after accepting a commission, or only after orders have been received to report to camp for service?

R. L., Nebraska.

Answer.—It is not proper for medical officers to wear the uniform until ordered to active duty.

Medical Education and State Boards of Registration

COMING EXAMINATIONS

Arizona: Phoenix, Oct. 1. Sec., Dr. Allen H. Williams, 219 Goodrich Bldg., Phoenix.

Arkansas: Little Rock, Nov. 12-13. Sec., Regular Bd., Dr. T. J. Stout, Brinkley, Ark.; Sec., Eclectic Bd., Dr. C. E. Laws, 803½ Garrison Ave., Ft. Smith.

California: Sacramento, Oct. 21-24. Sec., Dr. C. B. Pinkham, Butler Bldg., San Francisco.

Colorado: Denver, Oct. 1. Sec., Dr. David A. Strickler, 612 Empire Bldg., Denver.

Connecticut: New Haven, Nov. 12-13. Sec., Regular Bd., Dr. C. A. Tuttle, 196 York St., New Haven; Sec., Eclectic Bd., Dr. James E. Hair, 730 State St., Bridgeport; Sec., Homeopathic Bd., Dr. E. C. M. Hall, 82 Grand Ave., New Haven.

District of Columbia: Washington, Oct. 8. Sec., Dr. Edgar P. Copeland, The Rockingham, Washington.

Georgia: Atlanta, Oct. 8-9. Sec., Dr. C. T. Nolan, Marietta.

Idaho: Boise, Oct. 1-2. Sec., Dr. Ray H. Fisher, Rigby.

Kansas: Topeka, Oct. 8-9. Sec., Dr. H. A. Dykes, Lebanon.

Maine: Portland, Nov. 12-13. Sec., Dr. Frank W. Searle, 776 Congress St., Portland, Me.

Massachusetts: Boston, Nov. 12-14. Sec., Dr. Walter P. Bowers, No. 1 Beacon St., Boston, Mass.

Michigan: Lansing, Oct. 8-10. Sec., Dr. B. D. Harison, 504 Washington Arcade, Detroit.

Minnesota: Minneapolis, Oct. 1-4. Sec., Dr. T. McDavitt, 741 Lowry Bldg., St. Paul.

Missouri: Kansas City, Sept. 30-Oct. 2. Sec., Dr. George H. Jones, State House, Jefferson City.

Montana: Helena, Oct. 1. Sec., Dr. S. A. Cooney, Power Bldg., Helena.

Nevada: Carson City, Nov. 4. Sec., Dr. S. L. Lee, Carson City.

New Jersey: Trenton, Oct. 15. Sec., Dr. Alex. MacAlester, 438 E. State St., Trenton.

New Mexico: Sante Fe, Oct. 14. Sec., W. E. Kaser, East Las Vegas.

Oklahoma: Oklahoma City, Oct. 8-9. Sec., Dr. J. J. Williams, Weatherford.

Rhode Island: Providence, Oct. 3. Sec., Dr. B. U. Richards, 315 State House, Providence.

Utah: Salt Lake City, Oct. 7-8. Sec., Dr. G. F. Harding, 405 Templeton Bldg., Salt Lake City.

Dental Colleges Classified

At the annual meeting of the Dental Educational Council of America, held in Chicago, July 31, 1918, a classification of the dental colleges in the United States was completed. The list as just furnished us by Dr. Henry L. Banzhaf, the secretary of the Council, is as follows:

CLASS A

Creighton University, College of Dentistry, Omaha, Neb.
Harvard Dental School, Boston, Mass.
Marquette University, College of Dentistry, Milwaukee, Wis.
Medical College of Virginia, School of Dentistry, Richmond, Va.
North Pacific Dental College, Portland, Oregon.
Ohio State University, College of Dentistry, Columbus, Ohio.
The Thomas W. Evans Museum and Dental Institute, University of Pa.
Tufts Dental College, Boston, Mass.
University of California, College of Dentistry, San Francisco, Calif.
University of Illinois, College of Dentistry, Chicago, Ill.
University of Iowa, College of Dentistry, Iowa City, Iowa.
University of Michigan, College of Dentistry, Ann Arbor, Mich.
University of Minnesota, College of Dentistry, Minneapolis, Minn.
University of Pittsburgh, College of Dentistry, Pittsburgh, Pa.
University of Southern California, College of Dentistry, Los Angeles.
Northwestern University Dental School, Chicago, Ill.

CLASS B.

Colorado College of Dental Surgery, Denver, Colo.
Georgetown University, School of Dentistry, Washington, D. C.
Howard University Dental School, Washington, D. C.
Atlanta-Southern Dental College, Atlanta, Georgia.
Louisville University, College of Dentistry, Louisville, Ky.
Chicago College of Dental Surgery, Chicago, Ill.
Indiana Dental College, Indianapolis, Ind.
Loyola University, School of Dentistry, New Orleans, La.
Tulane University, School of Dentistry, New Orleans, La.
Baltimore College of Dental Surgery, Baltimore, Md.
University of Maryland, Dental Department, Baltimore, Md.
St. Louis University, College of Dentistry, St. Louis, Mo.
Washington University Dental School, St. Louis, Mo.
Kansas City, Dental College, Kansas City, Mo.
Western Dental College, Kansas City, Mo.
University of Buffalo, Dental Department, Buffalo, N. Y.
New York College of Dentistry, New York.
College of Dental and Oral Surgery of New York.
Western Reserve University Dental School, Cleveland, Ohio.
Ohio College of Dental Surgery, Cincinnati, Ohio.
Philadelphia Dental College, Philadelphia, Pa.
Vanderbilt University, School of Dentistry, Nashville, Tenn.
University of Tennessee, College of Dentistry, Memphis, Tenn.
Meharry Dental College, Nashville, Tenn.
George Washington University Dental School, Washington, D. C.

College of Physicians and Surgeons, Dental Dept., San Francisco, Calif.
Baylor University Dental Department, Dallas, Texas.

CLASS C

Lincoln Dental College, Lincoln, Neb.
College of Jersey City, N. J.
Cincinnati College of Dental Surgery, Cincinnati, Ohio.
Texas Dental College, Houston, Texas.

Connecticut July Examination

Dr. Charles A. Tuttle, secretary of the Connecticut Medical Examining Board, reports the practical and written examination held at New Haven, July 9-10, 1918. The examination covered 7 subjects and included 70 questions. An average of 75 per cent. was required to pass. Of the 23 candidates examined, 17 passed and 6 failed. The following colleges were represented:

College		Year Grad.	Per Cent.
	PASSED		
Yale University		(1918)	77.9, 79.6, 84.7, 85.3
Georgetown University		(1918)	79.6, 85.9
Johns Hopkins University		(1917)	76.2, 77.3
University of Maryland		(1916)	75.1
Harvard University		(1918)	75.2
Tufts College Medical School		(1918)	75, 79.7
Columbia University	(1913) 82.1; (1917) 79.6;	(1918)	83.9
Cornell University		(1918)	81.9
University and Bellevue Hosp. Med. Coll.		(1918)	79.5
	FAILED		
College of Phys. and Surg., Los Angeles		(1912)	63.6
University of Louisville		(1917)	71
Tufts College Medical School		(1918)	68.7
Jefferson Medical College		(1905)	67.5
University of Vermont		(1914)	67.1
National University, Athens		(1911)	57.3

Connecticut Homeopathic July Examination

Dr. E. C. M. Hall, secretary of the Connecticut Homeopathic Medical Examining Board, reports the written examination held at New Haven, July 9, 1918. The examination covered 7 subjects and included 70 questions. An average of 75 per cent. was required to pass. One candidate was examined, who passed. One candidate was licensed by endorsement. The following colleges were represented:

College	PASSED	Year Grad.	Per Cent.
Hahnemann Med. Coll. and Hosp. of Philadelphia		(1918)	79

College	LICENSED BY ENDORSEMENT	Year Grad.	Endorsement with
Hahnemann Med. Coll. and Hosp. of Philadelphia		(1911)	New York

Connecticut Eclectic July Meeting

Dr. James E. Hair, secretary of the Connecticut Eclectic Medical Examining Board, reports that 2 candidates were licensed through reciprocity at the meeting held at New Haven, July 9, 1918. The following colleges were represented:

College	LICENSED THROUGH RECIPROCITY	Year Grad.	Reciprocity with
Eclectic Medical Coll. of the City of New York		(1907)	New York
Eclectic Medical Institute		(1906)	Texas

District of Columbia July Examination

Dr. Edgar P. Copeland, secretary of the Board of Medical Supervisors of the District of Columbia, reports the oral and written examination held at Washington, July 9-11, 1918. The examination covered 16 subjects and included 80 questions. An average of 75 per cent. was required to pass. Of the 16 candidates examined, 14 passed and 2 failed. One candidate was licensed through reciprocity. The following colleges were represented:

College		Year Grad.	Per Cent.
	PASSED		
Georgetown University		(1918)	82.8, 89.9
George Washington University		(1918)	80.5, 81.2, 85.5, 88.6, 89.1
Howard University	(1915) 85.8; (1917) 80.3, 82.4, 86.1;	(1918)	79.4, 85.8, 88.4.
	FAILED		
Howard University		(1907)	59.1
University of Maryland		(1917)	70.7

College	LICENSED THROUGH RECIPROCITY	Year Grad.	Reciprocity with
Georgetown University		(1908)	Maryland

Book Notices

Surgery of the Spine and Spinal Cord. By Charles H. Frazier, M.D., Sc.D., Professor of Clinical Surgery and Surgeon to Hospital of University of Pennsylvania. With the collaboration of Alfred Reginald Allen, M.D., Associate in Neurology and Neuropathology, University of Pennsylvania. Cloth. Price, $8. Pp. 971, with 386 illustrations. New York: D. Appleton & Co., 1918.

As one reads the pages of this book, one does so with a sense of increasing satisfaction. The bringing together of the essentials of anatomy, normal and pathologic physiology, various methods of examination and the surgery of the cord in one volume is an enormous undertaking and one for which the medical man and the surgeon should thank the man who has accomplished it. The chapter on spinal tumors is interesting and complete. There is a feeling of increased optimism in treatment after reading this portion of the work. In the section on surgery of the spinal roots the discussion of gastric crises in tabes dorsalis and operative relief is dwelt on at length in the hope of better things in the future development of this field of surgery. This monograph is one of the hopeful signs in American medical literature. The author has limited himself to a definite field and dealt with it so comprehensively that the volume should stand as a landmark for some time to come.

Thyroid and Thymus. By André Crotti, M.D., F.A.C.S., LL.D., Surgeon to Grant and Children's Hospitals, Columbus, Ohio. Half morocco. Price, $10. Pp. 567, with 129 illustrations. Philadelphia: Lea & Febiger, 1918.

This work presents in a fairly satisfactory manner a general review of the thyroid and thymus questions, but it cannot be said that anything materially new has been added to our knowledge of the subject. The book reminds one very much of a basket of berries in which all the good ones are placed on the top layer. It has a beautiful mottled red cover and heavy glazed paper, both of which may add to the cost of the book without increasing its value.

The Control of the Drink Trade. A Contribution to National Efficiency, 1915-1917. By Henry Carter. With a preface by Lord D'Abernon. Cloth. Price, $2.50 net. Pp. 323, with 19 illustrations. New York: Longmans, Green & Co., 1918.

In this interesting study of a great social and economic problem, the author describes the conditions that led the British government to regulate the use and sale of alcoholic liquors in Great Britain—a measure dictated by military necessity. The development of complete national control is traced from the early days of the war when work in the shipyards, in the munitions factories and in the transport areas was greatly hampered by drinking among the battleship workmen, crews, dock laborers and porters. The control began in a limited area of Great Britain, but as it was soon found that liquor was easily obtained from a zone outside this area, the regulation was extended by 1917 to every part of the island. The hours during which drink might be sold were curtailed by more than one-half the usual day in Scotland and by about two-thirds the usual day in England and Wales. Treating was prohibited, spirits were diluted, "credit" trade in liquor was cut off, and registered clubs were placed under the same regulations as licensed liquor houses. The control board did not confine its work to restrictive action, however. The author devotes some interesting pages to its constructive activities, which include regulation of the public sale of food served without intoxicating liquors; improvement of licensed houses, on the theory that more wholesome surroundings will promote temperance; the establishment of rival attractions, such as bowling greens, reading rooms and moving pictures, and provision for the holding of trade union meetings elsewhere than on licensed premises. Among the results of government regulation, the author emphasizes increased sobriety, a decrease in the number of convictions for drunkenness and of attempted suicides, and above all, a marked decline in the death rate not only from alcoholism but also from cirrhosis of the liver. In 1916, when national regulation became general, the number of certified deaths from alcoholism was 47 per cent. less, and that from cirrhosis of the liver was 26 per cent. less than in 1914. As a guide to other countries wishing to make what has been called "the greatest social experiment of modern times," the book should be most valuable.

Social Medicine, Medical Economics and Miscellany

State Care of Mental Defectives

According to a survey of Nassau County, New York, made by Dr. A. J. Rosanoff in 1916, the proportion of mental defectives to the general population is one in every 183 people. This large proportion is not alarming, in view of the fact that a considerable percentage of these defectives are not seriously enough affected to require institutional care. They do, however, need medical and psychologic advice from trained specialists in mental diseases, and in his interesting study of "The Problem of the Mental Defective and the Delinquent," Dr. C. L. Carlisle points out how this aid may be the most effectively given in state clinics for mental hygiene. He recommends that these clinics, unlike both public and private clinics already established, be kept open daily. They should not be considered as interfering in any way with the development of institutional clinics, which have a special field limited by the needs of their respective institutions. They should be distributed throughout the state with reference to the needs of the adjacent population. They should provide advice and treatment for the patients, educate the parents and friends of the patients on topics of mental hygiene, and act as a clearing house for cases subject to examination for state institutions and as a way station for patients discharged from those institutions. Each clinic should be directed by a well educated physician with general hospital experience, as well as experience in mental and nervous disorders, whose appointment should come as a result of a civil service examination. In addition, there should be a field worker for each clinic, also under civil service regulations, for the purpose of investigating family histories, following up paroled patients, and the like. The chief of the clinic should try to enlarge its field of usefulness by delivering lectures to the general public and bringing technical facts before the medical profession and facts of sociologic value before lay and civic bodies. One of its duties should be the proper disposal of patients brought before it, some of whom must be sent to hospitals for the insane, and others of criminal tendencies back to the courts for trial. In discussing the treatment of patients, Dr. Carlisle condemns the use of "disciplinary" measures, strong rooms and restricted diet as punishment, urging that such measures are antiquated and that "modern therapeutic methods adapted to abnormal mental states must be used." In order that the state may always know the number of mental defectives within its borders, he recommends a system of registration covering the various recognized fields of genetics and personality, under the auspices of the state board of charities.

Color Blindness

Studies were made by Dr. George L. Collins for the U. S. Public Health Service to determine the comparative value of the Jennings worsted skein tests and the Edridge-Green lantern test for color blindness, and to determine the effect, if any, of refractive conditions, lesions and anomalies of the eye, and also the effect of sex on different degrees of color perception. The examinations were made as a part of other studies of the effect of illumination on vision, conducted as a part of an illumination survey of the federal department buildings in Washington, D. C.

The Jennings test is a modification of the Holmgren test, and like it uses for test skeins, first, a green test skein of the color corresponding to that part of the spectrum in which those with abnormal sense for red or green see a neutral band, and secondly, a test skein of rose color made by dyeing the worsted with blue and red. The Edridge-Green lantern has seven slides containing specially prepared colored glasses and six others containing modifying glasses which may be placed in front of the colored glasses to simulate mist, fog or rain, and produce their modifying effects on signal lights in actual practice. The test is constructed on the principle of presenting colors which, while very easily named by the normal sighted, are most liable to be miscalled by the color blind.

Comparing the results of the Jennings test with the Holmgren tests, both tests detected the markedly color-blind dichromic, and both tests failed to detect the individual with shortening of the red end of the spectrum. Thirty-two persons either with normal color sense or with only such slight defects as to permit them to be passed as not color blind, and who passed the Holmgren test, made mistakes of some kind with the Jennings test. From this it would appear that persons who should be passed as of normal or nearly normal color sense are more apt to be rejected by the Jennings than by the Holmgren test.

The results of the test were too confusing to permit of definite diagnostic interpretation or to be considered final in determining accurately and definitely the presence of dangerous color blindness. The results were so contradictory as to make it impossible to decide whether a person could be considered fit for passing or should be rejected. Nothing more than a general idea was to be deduced from the results. It would appear that the Jennings test is quite inferior to the lantern tests, and the results are more confusing, more irregular, and more difficult of interpretation than those of the Holmgren test. It is impossible to lay down definite rules for the examiner to use in deciding when the examinee should be accepted or rejected, as can be done with the lantern tests. It may be concluded, then, that the Jennings test is not adapted for testing sailors and trainmen, and that its use in that way is dangerous. Collins believes, however, that this test has a distinct function, particularly during the present general state of warfare, and that it is an exceedingly ingenious and acceptable addition to the many forms of color testing apparatus now at our disposal.

The Elimination of Quinin by the Urine

Working with the urine of troops in the East, Porak (*Journal of Tropical Medicine and Hyiene*, 1918, **21,** 138) found that from 30 to 40 per cent. of ingested quinin was excreted in the urine, and further, that in cases under continuous treatment the cycle of elimination was comparable from day to day. There are three stages in the elimination of quinin; in the initial and terminal stages only traces are found, but in the middle stage, generally from the fourth to the tenth hour after absorption, there is a much increased elimination. In health the periods and modes of elimination are the same, no matter what the dose or mode of administration. When there are gastro-intestinal disturbances, such as vomiting and diarrhea in severe cases of malaria, quinin merely irritates the mucous membrane without being absorbed; hence giving it by mouth is contraindicated. In slight renal diseases there is but little change in quinin excretion. In severe nephritis, however, the alkaloid appears but slowly in the urine, and there is no third stage of elimination. When there is an enlargement of the liver in malaria it seems as if there is diminished retention by this organ, for the second stage of elimination in the urine comes on earlier. In cardiac insufficiency or decompensation only traces of quinin are found in the urine. In several cases of typhoid and leukemia, Porak found no alterations in the elimination of the drug. There is a marked diminution in the elimination of quinin in certain cases of malaria with cachexia and anemia. With improvement, the curve of elimination approaches normal, while if the condition of the patient becomes worse the elimination decreases. As the kidney is but slightly affected in malaria as a rule, and as the quinin rapidly disappears from the blood, there must be some fixation or retention in the organs in such cases. This retention appears to cause no harm, provided not more than 2 gm. are given daily.

In view of these observations it appears that for optimal effect it would be best in most cases to give quinin every three or four hours in approximately 0.25 gm. doses, preferably by mouth, except when there are gastro-intestinal disturbances, and here subcutaneous or intermuscular injection is indicated. Needless to say, the daily 2 gm. should be exceeded in cases of pernicious and primary malaria. The intravenous method should be employed in pernicious cases. The quinin treatment should be continued for several consecutive months with frequent intermissions, and the elimination by the urine should be watched.

Medicolegal

Rights and Duties Under Employer's Contract to Furnish Medical Services

(Crites v. Willamette Valley Lumber Co. (Ore.), 169 Pac. R. 339)

The Supreme Court of Oregon affirms a judgment in favor of the plaintiff, a former employee of the defendant company who sued it to recover $125 which he paid a surgeon for an operation and treatment when he had an attack of appendicitis and the company physician was out of town. The company had posted a notice which stated that in consideration of a hospital fee charged employees, each employee was entitled to full medical and surgical attendance and necessary medicines and appliances for the treatment of any injuries or sickness, all medical and surgical attendance to be furnished by the company physician or surgeon. The court says that the following facts and the legal conclusions resulting therefrom might be taken as indisputable: First, that the notice posted by the defendant and the payment by the plaintiff to it of the fees specified constituted a complete contract requiring the defendant to furnish the services of its physician to the plaintiff under the circumstances mentioned; second, that it was the duty of the plaintiff to apply for such service before employing another physician; third, it was the duty of the plaintiff to use reasonable diligence to find the company physician and request his services before employing another physician, and if he failed to use such diligence he could not hold the defendant. Whether or not he used such diligence was a question of fact for the jury to determine.

If the party requiring the services of a physician was ignorant as to who the physician was, it was his duty to inquire and ascertain from the company that employed him; but when the name and place of business or residence of the physician was known the injured should apply at the place where, under all the circumstances, it was reasonable to suppose the physician might be found. In this case the company physician had an office and a young woman attendant; also had his telephone so connected with that of an adjoining drug store that any call for his office also rang up the drug store, the employees in which in his absence were accustomed to give such information as to his whereabouts as might be necessary. But the plaintiff's wife went to the physician's residence at about 8 a. m., when it would be only reasonable to assume that he would be at his residence rather than at his office, and was informed that he was out of town. At 1:30 p. m. she went to a neighbor's and called up the physician's residence over the telephone, and was again informed that he was absent. Becoming alarmed concerning the plaintiff's condition, she called in the other surgeon. Under the circumstances the court is not prepared to say that there was any such lack of diligence on the part of the plaintiff, or his wife, as would preclude a recovery in this case.

There is no rule for the construction of this species of contracts different from the rules that apply generally to all contracts. So far as the defendant was concerned, it was in writing, and by its terms the defendant promised absolutely to furnish the services of its physician in case of sickness or injury. It was not a contract to furnish the services of its physician in the event he could be reached or was available, but to furnish his medical services when needed. The court does not wish to be understood as holding that under all circumstances it would be obligatory on the employer to have a physician at hand at the very hour or minute his services were required, or be responsible for the services of some other physician whom the employee might secure. The right to apply to another physician must depend on the circumstances and the urgency of the case. A man with a boil on his person might reasonably wait for a day for the service of a physician, while one suffering from a severe attack of appendicitis would be rash to wait for a single hour. The "rule of reason" applies here, as in all cases of a similar character. To say that having bought and paid the company for this service in advance, the plaintiff should be required to pay for it a second time and stand the loss, because the company was not in a position to furnish it, would not be just and would be to apply to this contract a rule not applied to other contracts.

Leaving Pad in Drainage Gauze—Admissible Evidence—Defining "Operation"

(Barrett's Administrator v. Brand (Ky.), 201 S. W. R. 331)

The Court of Appeals of Kentucky, on the second appearance before it of an appeal from a judgment for the defendant, affirms such judgment, in this action for alleged malpractice in an operation for chronic ovaritis. The court says that the patient showed signs of dissolution, and the cavity was hurriedly closed up to prevent it. A gauze drainage was arranged, and in it was one of the gauze pads, which was discovered four days later by the wound being opened up, at which time some of the parts, including some of the smaller intestines, were found to be inflamed and the patient shortly died. The chief act of negligence complained of was that of leaving the pad in the patient; but under the evidence and instructions of the court the jury found that this was not an act of negligence, or, if it was, it could not be termed the proximate cause of the patient's death.

It was insisted that there was error in permitting the professional witnesses to state, in substance, that the case was practiced according to the approved methods of the medical profession, and that, according to the opinions of those witnesses, the patient, in her diseased and run-down condition, would have died, and as a matter of fact did die, from those conditions, notwithstanding there might have been negligence in the manner complained of. It is, of course, fundamental that although an act may be negligent and involve a violation of duty, still, before a cause of action can be predicated thereon, the injury flowing therefrom must have been the proximate result of such derelictions. While it was not denied in this case that the pad was overlooked and left in the patient's body, yet it was clear that it was confined in the drainage gauze, which was an essential and necessary part of the operation, and it was therefore not in a condition to produce injurious consequences. But, however that might be, the rule is that while an expert witness may not take the place of the jury by stating whether certain acts constitute negligence, he may give his opinion in regard to matters which require scientific or specialized knowledge or experience, and for which the general common sense and practical experience of the jury are inadequate. The defendant's expert witnesses were permitted to state whether in their opinion the case was practiced according to the approved methods of surgery, but they were not asked, nor were they permitted to state, whether any particular act done or omitted to be done was or was not a careless or negligent one. According to the court's view, there is quite a distinction between whether a case has been practiced according to the rules of surgery and whether those rules or any of them are dictated by the soundest prudence and the most careful considerations. A case might be practiced according to such approved methods of surgery, and still not be characterized by careful and prudent action, and the court is clearly of the opinion that the complained of questions and answers did not invade the province of the jury and were proper subject-matters of injury of the expert witnesses.

Objection was made to evidence given by some of the assisting physicians concerning statements made by the defendant relating to the conditions which he found, and other subjects connected with the operation, during and while he was performing it. But this objection was untenable because the evidence complained of constituted a part of the res gestae or essential circumstances of the case growing out of the main transaction, which was the operation, and serving to explain it.

It was claimed in regard to the instructions that the court should have defined what constituted an operation, that is, that the court should have said to the jury in its instructions that the operation commenced at the beginning of making the incision and ceased when the incision was closed; but this court does not regard the term "operation" to be one of such technical meaning as to require a definition at the hands of the court. Every act necessary to its performance is included within the known meaning of the term.

Burden of Proof in Prosecution for Unlawfully Practicing Medicine

(Denton v. State (Tex.), 201 S. W. R. 183)

The Court of Criminal Appeals of Texas, which reverses a judgment of conviction of defendant Denton and remands the cause, says that the conviction was for practicing medicine in violation of Article 750 of the Penal Code, which makes it unlawful for any one to practice medicine "who has not registered in the district clerk's office of the county in which he resides, his authority for so practicing, . . . verified by oath." The statute also contains a statement that the clerk shall indorse on the certificate the fact that the oath has been made and recorded, and concludes as follows:

> The holder of the certificate must have the same recorded on each change of residence to another county, and the absence of such record shall be prima facie evidence of the want of possession of such certificate.

There was no evidence introduced to the effect that the defendant's authority had not been registered as required by the statute. It is not unlawful to practice medicine, but it is unlawful to do so without compliance with the statute. The offense is the practice of medicine without compliance with the statute, and the burden is on the state to prove the offense. There will be found decisions of other states holding that, under certain circumstances, the burden of making proof of authority to practice medicine is not on the state because a fact within the peculiar knowledge of the accused. Such is not the case here, as the statute itself prescribes a rule of evidence making the absence of the record prima facie evidence of the want of such certificate; and requiring that the certificate be recorded in the county in which the accused is residing at the time renders it easy for the state to make the proof of records of the particular county. The failure to make the proof in this instance characterized the evidence as insufficient. But the defendant's suggestion that the evidence showed that the occupation in which he was engaged was that of a masseur and exempted by Article 754 of the Penal Code from the provisions of Article 750 could not, the court thinks, be sustained as a matter of law. The character of his occupation was a question of fact.

7 *Effect of Injections of Pituitary Solution on Urinary Output in Case of Diabetes Insipidus. S. W. Clausen, St. Louis.—p. 195.

1. **Immunity Reactions in Hydrated and Concentrated Tissue.**—The work Schlutz reports was undertaken to show whether there was any difference in the defensive mechanism of hydrated or concentrated tissue, using determinations of immune reactions as an index. The lysin reaction was compared in fifteen fat animals and eighteen lean animals. The animals were immunized against blood cells by intraperitonal inoculations. About 0.25 c.c. of washed blood cells were injected intraperitoneally at from two to three day intervals. Two weeks following the third or fourth injection the animals were exsanguinated, the blood allowed to clot, and then centrifuged in order to separate the serum from the clot. The serum was then diluted with salt solution 1:10, and its lytic titer determined in the usual way. The precipitin reaction was carried out on eleven fat and eleven lean animals. The animals were treated with from 0.25 to 0.5 c.c. of ascitic fluid or human blood serum intraperitoneally as was done with the lysin pigs. The precipitin titer of the serum was then determined by the dilution method. The agglutination was determined in seven fat and seven lean animals. The procedure was much the same as in the precipitin reaction. Pigs were inoculated intraperitoneally with a twenty-four hour killed culture of the typhoid bacillus. Four injections were made at three or four day intervals. Ten days following the last injection the titer of the serum was determined by the dilution method. The lysin reaction was negative or nearly so in practically all of the fat animals, but was positive, sometimes to a marked degree, in over 60 per cent. of the lean pigs. The precipitin reaction was uniformly negative in both the fat and lean series. The agglutinin reaction, while present in only 11 per cent. of the fat animals, was positive in over 70 per cent. of the lean animals. The lysin and agglutinin reaction would seem to indicate that there is a difference in favor of concentrated tissue and that the theoretical considerations expressed by Czerny and other observers are substantially correct.

4. **Syphilitic Meningitis Cured by Arsphenamin and Mercury.**—A boy, 10 years of age, was well up to March 1, 1917, when he fell from the roof of a standing freight car, striking on his head. After the accident he seemed in great pain for several hours. During the night he had a chill and vomited until morning. Two weeks later he commenced to have crying attacks and twitching and pain in the left arm. These emotional attacks increased in severity and were associated with convulsions, which occurred every second night. Four months after the injury (July 10) the patient entered the hospital as a case of epilepsy. During the first ten days of his stay he had one convulsion, frequent screaming attacks and periods of maniacal excitement. He cried, swore and talked incoherently, and complained of pain and muscular twitching in his left arm. After a few days it was noticed that his movements were awkward and constrained; that he held his head and back very rigidly, the head being inclined to the right. The knee jerks were very active; ankle clonus of right leg; Kernig sign present, most marked on right side;

muscles of arms and legs very spastic. The pupils were widely dilated; reacted to accommodation but not to light. There was a double optic neuritis of 2 diopters, each side. Leukocytes, 9,350; hemoglobin, 80 to 90 per cent. The spinal fluid contained 406 cells per cubic millimeter. Globulin and albumin were each + + + +; Wassermann, + + + +. The father and mother each showed a Wassermann + +. The child was evidently suffering from a syphilitic cerebrospinal meningitis. He was given daily inunctions of mercury and arsphenamin every one or two weeks. After the first dose of arsphenamin there was a prolonged chill and fever of 102 F., the only rise of temperature in the disease. About December 24, the Wassermann was negative, and the optic neuritis had disappeared. The boy was sent home and attended school regularly. In April he complained of frequent momentary headache. The spinal fluid, however, was negative to the Wassermann and colloidal gold tests. About May 1, the optic disks were normal. On May 14, fourteen months after the beginning of symptoms, the child was free from all symptoms and had been for seven months. Neither the parents nor the child had any symptoms of syphilis, hereditary or acquired. The fall on the head acted as a provocative agent causing cerebrospinal symptoms in a case of presumably latent hereditary syphilis. The lesion in the cerebrospinal meninges was probably a proliferative gummous leptomeningitis involving the cortex and spinal meninges; also an ependymitis with an increase of cerebrospinal fluid and some hydrocephalus. The choked disks were due to intracranial pressure from fluid and not to a direct inflammation of the optic nerve. Decompression and aspiration were followed by no immediate relief save that the lessening of intracranial pressure gave the cerebral circulation a little more freedom. The patient was very responsive to treatment; the acute symptoms lasted about three months. Mercurial inunctions were given every day for five months and arsphenamin at first every week; later every two weeks.

7. **Effect of Pituitary Solution on Urinary Output in Diabetes Insipidus.**—A study was made by Clausen of the urinary output of a 9½ year old boy suffering from diabetes insipidus, as influenced by injections of pituitary solution. Following injections of from 0.25 to 1 c.c. of surgical pituitary solution, there is a marked diminution of the urine volume. This diminution persists for from five to six hours, sometimes much longer. The volume of night urine is reduced when pituitary solution is injected at any time on the preceding day. The hourly rate of elimination of chlorids is always reduced after injections of pituitary solution. The hourly rate of elimination of urea is usually only slightly, if at all, reduced by injection of pituitary solution. The hourly rates of elimination of creatinin and uric acid are only slightly reduced by injection of pituitary solution. The hourly rate of elimination of titratable acids in the urine is only slightly influenced by these injections. The hourly rate of elimination of no substance studied is increased by injections of pituitary solution. When the hourly ingestion of water and sodium chlorid or urea is maintained at a constant high level, the urea elimination is quite uninfluenced by the injection of pituitary solution, whereas, the chlorid elimination is considerably diminished, and the water elimination very much diminished. Pituitary solution injections in diabetes insipidus control urine output primarily and thirst secondarily.

8. **Fever at Time of Labor.**—The histologic picture presented by the placenta was studied by Slemons in thirty-four cases. Typically, the bacteria are found in the subamniotic connective tissues where they come in contact with the large fetal blood vessels which cross the surface of the placenta. Occasionally, it is possible to demonstrate bacteria in the act of penetrating the walls of the vessels. In most instances the epithelium covering the villi is intact; the capillaries within the villi are normal and bacteria are not demonstrable on the surface or in the interior of the villi. Under these circumstances, it is evident that the infection does not proceed from the maternal circulation and does not pass through the walls of the villi. Bacteria enter the placenta by way of the amniotic membrane and the amniotic fluid. Generally, the latter becomes infected because the membranes rupture prematurely, labor is prolonged and repeated vaginal examinations are made. In one series of 600 labors, Slemons noted placental bacteremia in ten instances; and in another series of 1,000 labors it occurred twenty-four times. On this basis, he estimates its frequency as 2 per cent. of all labors at term. In other words the incidence of placental bacteremia and of intrapartum fever is identical. Slemons urges that as a matter of routine, the placenta should be subjected to careful examination, especially in hospital practice. The examination should not be limited to the gross study of the organ to determine its weight, dimensions and complete separation from the uterus. Portions should be selected for microscopic study. Placental bacteremia explains a great many of the fetal and infant deaths heretofore impossible of explanation.

9. See abstract in The Journal, April 13, 1918, p. 1118.

10 and 14. Abstracted in The Journal, June 22, 1918, p. 1976.

15. *Myomata Uteri.*—All of the 1,500 patients whose cases were analyzed by Broun had some form of hysterectomy or myomectomy. As a result of the operations, twenty-eight patients (1.86 per cent.) died; of these seven died from embolus, chiefly between the eighth and twentieth day, seven from peritonitis, and the remainder from various causes. Sixty-six malignant conditions were found. There were fifty-eight cases of associated ovarian pathology. There were 265 cases of associated tubal disease, the majority of which would have required at some time surgical interference. Tuberculous endometritis was present in two instances, and in 105 myomas, necrotic or calcareous changes were present. One hundred and sixty-seven chronic or subacute inflammatory appendixes were found. There were nine instances of associated extra-uterine pregnancy and fifty-one of normal pregnancy. Three hundred and fifty-five cases, 23.7 per cent., contraindicated the use of radium and roentgen ray. The average therefore of 23.5 per cent., or practically one out of every four patients seeking relief from symptoms resulting from the presence of uterine myoma, have also some other pathologic condition that would contraindicate the use of radium and roentgen ray. After a review of the cases and noting the coincident conditions, Broun is convinced that the symptoms on account of which the majority of patients entered the hospital were due in the greatest measure to conditions outside of the uterus and not to the presence of the tumor itself, unless it was from hemorrhage. That radium and roentgen ray have their field in gynecology is unquestionable. Broun believes, however, that this field should be limited to cases in which it is inadvisable to do any form of

operation and to hemorrhage of myopathic origin or from small and absolutely uncomplicated myomas of the uterus.

16. **Roentgen Therapy of Fibroids of Uterus.**—This report covers a series of thirty-two cases of fibroids up to Oct. 1, 1917, which were subjected to massive roentgen-ray exposures on account of severe menorrhagia. The tumors varied in size, some reaching above the umbilicus and filling the entire abdomen. All were under observation and the diagnosis positively established before treatment was instituted. Permanent amenorrhea resulted in twenty-five, or 78 per cent., and temporary amenorrhea in seven, or 22 per cent. Four of the seven patients were between 30 and 40 years of age and the character of the uterine bleeding was that of a scanty regular menstruation; in the other three, the flow was very irregular, small in amount and occurred at intervals of from three to six months. In nearly every case a decided reduction in the size of the uterus was perceptible; in some no vestige could be detected of former large fibroids. Brettauer concludes that at an age below 45 the roentgen-ray treatment for fibroids should not be the choice, but should be employed only when operative measures are not advisable or are refused. Between the ages of 45 and 55, roentgen-ray treatment should be the method of choice and no patient should be deprived of the right to undergo it. Uterine hemorrhages due to fibroids in women beyond the age of 55 should raise a suspicion of sarcomatous degeneration and operative measures are preferable to any other form of treatment.

28. **Etiology of Epidemic Poliomyelitis.**—Streptococci have been isolated by Tsen and his associates from the central nervous system of monkeys dead of poliomyelitis and from the central nervous system of monkeys dead of other causes, as well as from the brains of normal rabbits. Streptococci isolated from poliomyelitic monkeys do not differ from those isolated from monkeys and rabbits dead from other causes. An etiologic relation has not been established between streptococci and poliomyelitis. Several times an organism was isolated that was similar to the globoid bodies culturally, morphologically, and in staining reaction, but it could not be carried along for more than three generations. The pathogenicity of these organisms has therefore not been tested on monkeys. Typical lesions of poliomyelitis were not produced in rabbits by the injection of either the poliomyelitic virus or streptococci.

30. **Effect of Temperature on Complement Fixation Reaction in Syphilis.**—*Noguchi says that the examination of syphilitic serum or cerebrospinal fluid can be made at any temperature between 23 and 37 C. The velocity of the fixation reaction, including the fixation of complement and subsequent hemolysis, is greater at a higher temperature, the optimum point being 37 C. The maximum reaction is also reached, however, when the mixture of lipoids, syphilitic serum, and complement is allowed to stand for a long enough period at a lower temperature, the minimum thermal point being near 23 C. For the optimum temperature (37 C.) an incubation of thirty minutes is sufficient, while for the minimum temperature (23 C.) two hours are necessary. At the temperature 30 C. the reaction proceeds with moderate velocity and is complete within sixty minutes. Guinea-pig complement gave a sharper reaction with the serums which contained less than one unit of the fixing substance. Fixation is complete, however, at any of the three temperatures within twenty minutes when there are more than two units present. A serum containing one unit of fixing substance will complete reaction within thirty minutes at 37 C., sixty minutes at 30 C. and two hours at 23 C., irrespective of whether human or guinea-pig complement is used. For many reasons a properly adjusted thermostat for 37 C. is recommended for conducting the serum diagnosis of syphilis when possible, but it should not be overlooked that at a temperature near 30 C. an entirely reliable result can be obtained without a special incubator. Even at a temperature as low as 23 C. the test can be carried out if sufficient length of time is allowed. These conclusions refer only to the systems in which the acetone insoluble fraction of tissue lipoids is used as antigen.*

31. **Restorative Effects of Salts of Magnesium and Calcium.**—The experiments presented by Gates brought out the following facts. Intramuscular injections of sodium oxalate into rabbits in doses of 0.18 and 0.2 gm. proved to be invariably fatal, death generally occurring in a comparatively short time. The symptoms consisted in excitation and tonic and clonic convulsions of diminishing strength if death was delayed. Some animals succumbed in the first convulsion. From the experiments in which magnesium or calcium was added, it was evident that massage of the site of the oxalate injection is unmistakably an aggravating factor. In the experiments with the addition of magnesium or calcium, doses of 0.2 gm. of ovalate were used, with or without massage. There was practically in all cases clear evidence that the effect of the additional injections was in the nature of an antagonism to the oxalate effects. An injection of 0.6 gm. of magnesium not only alleviated or abolished the excitation and convulsions, characteristic of oxalate poisoning, but also reduced the mortality by 30 per cent. When the dose of magnesium was only 0.4 gm. per kilogram of body weight and the site of the injection of the oxalate was not massaged—a condition in which 0.2 gm. of oxalate alone was invariably fatal—the mortality was reduced by 80 per cent. The favorable effect of injections of calcium chlorid depended on the quantity injected and the length of the interval elapsing between the injection of the oxalate and that of the calcium. When the site of the oxalate was massaged and only 5 c.c. of the calcium solution were injected, the animals succumbed to the oxalate poisoning. When 10 c.c. of calcium were given one minute after the oxalate injection, the animals survived. When the site of the oxalate injection was not massaged, then even 5 c.c. of the calcium were sufficient to save life.

32. **Urobilin Elimination.**—*Dubin found that the output of urobilin is increased in experimental trypanosome anemia, presumably as a result of the increased blood destruction. The administration of arsphenamin during the anemic period, if it checks the blood destruction, reduced the urobilin elimination, but this result does not follow unless the blood picture improves. Following splenectomy in the normal dog an increase in the urobilin elimination of varying degree occurs, the significance of which is doubtful. Splenectomy during the period of anemia does not cause a decrease in*

urobilin elimination. The experiments support the view that the elimination of urobilin may be considered as an index of blood destruction, but they do not explain the decrease in the elimination occurring in man in certain forms of hemolytic anemia following splenectomy.

34. **Nuzum's Antipoliomyelitic Serum.**—The value, in general, of antistreptococcic serums in combating streptococcus infections is unproved. The antistreptococcic serum of Nuzum and Willy has failed to show in the monkey neutralizing or therapeutic power when applied by their methods against small doses of the virus of poliomyelitis. Under the same conditions the serum of monkeys recovered from experimental poliomyelitis proved neutralizing and protective. The experimental and other evidence adduced by those who regard the streptococcus as playing an essential part in the pathology of epidemic poliomyelitis and the antistreptococcic serums as exhibiting therapeutic properties for man and monkeys is regarded by Amoss and Eberson as being imperfect and inconclusive.

37. **Quantity of Secreting Tissue in Living Kidney.**—Under the strain induced by the administration of urea, the authors were able to demonstrate the relation between the degree of anatomic damage in the kidney and the degree of defect in the urea-excreting capacity induced by uranium. The closest correlation between structure and function was obtained when the ratio between the urea content of the urine and of the blood was used as the measure of function.

48 *Protective Properties of Antipoliomyelitic Horse Serum. J. W. Nuzum, Chicago.—p. 309.

38. **Precipitin Reaction in Urine in Pneumonia.**—Quigley has made study of the sputum for the type of infection, and of the urine for precipitin reactions in 100 cases of lobar pneumonia due to the pneumococcus, occurring in Chicago during the winter of 1917-1918. There were 33 instances of infection with pneumococci of Type I, 36 of Type II, 13 of Type III, and 18 of Type IV. Of eighty-two cases of Types I, II and III, the urine of sixty-seven showed at some time during the disease a specific precipitin reaction. The strength of the reaction gradually increased during a period of three or four days, persisted from two to nineteen days, and gradually disappeared. It was present during the third week in a few convalescents when discharged from the hospital. Thirty of the 100 patients died. The group mortality was approximately 39, 36, 8 and 17 per cent., respectively, for the four types. Of the twenty-seven deaths due to Types I, II and III infections, twenty-three showed a precipitin reaction in the urine; four were negative. Of the sixty-seven showing a precipitin reaction twenty-three, or 34 per cent., died. Of the fifteen with negative reactions four, or 27 per cent., died. It therefore appears that a large percentage of fatal cases of pneumonia have a substance in the urine capable of giving a specific precipitin reaction with antipneumococcus serum, but that the presence of this substance in the urine is not of great unfavorable prognostic value, as the mortality when it could not be demonstrated was only slightly lower than when it was present.

39. **Effect of Culture Medium on Agglutinative Properties of B. Paratyphosus B.**—The effect of the medium on the agglutination of *B. paratyphosus* B was studied by Victorson. The mediums tested were sugar-free agar as a control medium, 10 per cent. rabbit blood agar, Loeffler's serum, 1 per cent dextrose and 1 per cent. lactose broth and agar, potato, and Jordan's nonprotein medium to which was added 1.5 per cent. agar. The reaction of the sugar mediums and sugar-free agar was 0.5 per cent. acid to phenolphthalein. The organism was transferred forty-four times. The following results were obtained: Each strain, as a rule, agglutinated better with its homologous serum than with any heterologous serum. The serum produced by the potato strain, however, was an exception, since it agglutinated the organisms grown in dextrose broth and on Loeffler's serum better than its own strain. The variations in agglutination were not marked, consisting merely of slight differences in the highest dilutions to which the strains are agglutinated.

40 **Methyl Red and Voges-Proskauer Reactions.**—In the routine analysis of sixty-eight water samples from private and public supplies received from many sections of the state Stovall and Nichols isolated 200 cultures which fulfilled the requirements of the completed test for members of the colon group of organisms of the Standard Methods of Water Analysis. They found that 120 of these reacted acid to methyl red, thirty-eight gave a Voges-Proskauer positive reaction, and that forty-two gave irregular reactions. The intensity of these reactions varied considerably.

41. **Toxic Substance from Lung Tissue.**—The method described by Wherry and Ervin of producing accelerated respiration or death was discovered accidentally in an experiment with tuberculous tissue from a rabbit's lung. A piece of the tissue, 6 by 8 mm., filled with tubercles, was ground up with sand, suspended in 8 c.c. of 0.9 per cent. sodium chlorid solution, centrifuged to remove coarse particles, and 1 c.c. of the supernatant fluid injected intravenously into another rabbit, which immediately fell on its side with marked inspiratory dyspnea, followed by convulsions and opisthotonos, and died a few second later. Rabbit lung is more fatal for the rabbit than for the guinea-pig and vice versa. Many of the symptoms of anaphylactic shock are produced—the acceleration of the respiration and peripheral irritation, both best shown by sublethal doses, the inspiratory dyspnea, the convulsions, the tolerance produced by graded repeated doses, the delay in the coagulation of the blood, all make one think of a possible relationship to anaphylaxis, but the lungs collapse on opening the thorax. Atropin does not protect. Morphin does not protect. Similar extracts of rabbit liver, kidney, ileum and spleen were harmless for rabbits. The lethal agent will not pass Berkefeld filter N at 600 mm. pressure. It is removed by animal charcoal. It is not extracted by ether. It can be removed by centrifugal force (36,000 revolutions per minute) and is apparently composed of, or adsorbed to, particles visible under the microscope. By beginning with a sublethal dose, and then injecting at short intervals thereafter larger doses, a rabbit will survive, without symptoms, several lethal doses. The authors are inclined to favor the idea that colloidal particles are responsible for the lethal action.

43. **Sporotrichosis Following Mouse Bite.**—An instance of an infection with *Sporotrichum schenckii* following the bite of a field mouse in North Dakota is described by Moore and Davis. The infection has persisted for about eighteen months, improving with administration of iodid and relapsing when the iodid is discontinued. Repeated sporo-agglutination tests gave positive results at serum dilutions varying from 1:320 to 1:80. At one time, when the patient had almost recovered, the test was slight at 1:20, but later became stronger. In general this test parallels the clinical course. Complement fixation tests made at various times generally yielded definitely positive results, corresponding thus to the agglutination

tests. In the icebox the antibodies in the serum retain their activity for over one year.

44. **Cultivation of Tubercle Bacillus from Sputum.**—Investigations were made by Corper and his associates to obtain cultures of tubercle bacilli for the study of their virulence and to gain information on the various steps involved in the technic of cultivating tubercle bacilli according to the method devised by Petroff. The routine cultivation of tubercle bacilli from microscopic positive sputum by Petroff's method, seeding two gentian violet egg medium tubes from each *sputum*, resulted in obtaining positive macroscopic cultures of varying grades on primary culture from 144 (27.3 per cent.) of 526 sputums. There was noted no relationship between the number of bacilli found in the original sputum and the percentage of positive growths obtained or their intensity. Egg medium prepared as directed by Petroff with fresh beef juice revealed no particular advantages over mediums in which was substituted sodium chlorid, beef extract, and peptone as used in ordinary broth. The inspissation of the Petroff gentian violet egg medium on three successive days also proved to have no advantages over a single autoclaving. Petroff's findings that the gentian violet egg medium is not suitable for the continued cultivation of tubercle bacilli was corroborated (24 per cent., six of twenty-five, failing to grow on two tubes in the first seeding and 43 per cent., six of fourteen, failing to grow on two tubes in the second seeding).

45. **Isolation of Bacilli of Typhoid Group from Feces.**—Since describing a method of preparing a brilliant green agar plating medium for the isolation of typhoid and paratyphoid bacilli from feces, the number of specimens examined by the authors has reached 7,111. Of this number 920 were endopositive and 1,235 were dye-agar positive. The results in the isolation of *B. paratyphosus* have been somewhat better than in the isolation of *B. typhosus.*

46. **Thermal Death Point of Pathogenic Streptococci.**—The thermal death point of twenty-seven strains of pathogenic streptococci from pathologic sources was never higher than 60 C. (140 F.) when heated in milk for thirty minutes. This fact seems to indicate that pathogenic streptococci are destroyed by the proper pasteurization of milk at 60 C. (140 F.) for a period of thirty minutes.

47. **Neutralizing Properties of Antipoliomyelitic Serum.**—Nuzum claims that antipoliomyelitic horse serum, prepared by repeated intravenous injections of the coccus isolated from the central nervous system in human and monkey poliomyelitis possesses neutralizing properties against the virus of poliomyelitis. The neutralizing properties of antipoliomyelitic horse serum in vitro for the virus of poliomyelitis afford a convenient and satisfactory test of the potency of this serum for use in the treatment of poliomyelitis. The neutralizing, protective and curative properties of antipoliomyelitic horse serum for experimental poliomyelitis of monkeys are in direct accord with the favorable results observed in the serum treatment of human poliomyelitis and argue strongly for the etiologic relationship of the coccus to this disease.

48. **Protective Properties of Antipoliomyelitic Serum.**—Nuzum has applied the therapeutic test, recently devised by Amoss and Eberson, to fresh samples of immune horse serum prepared by injections of the poliomyelitic coccus in the horse. Under the conditions of the test, three monkeys were completely protected while the fourth animal developed mild symptoms on the fourteenth day and subsequently recovered completely. The control monkeys receiving normal horse serum all developed a fatal poliomyelitis and died as early as the fourth day following injection of virus. Fresh immune horse serum protected perfectly against infection while pooled immune monkey serum served only to delay the onset of a fatal infection.

76. Abstracted in The Journal, Feb. 9, 1918, p. 414.

80. **Operation for Prolapse of Uterus.**—Collins sutures a transverse strip of the anterior aponeurosis of the abdominal rectus into the cervical trough formed after a supravaginal hysterectomy. The stumps of the broad ligaments are sutured to the posterior surface of the cervix and to each other. The cervix is thus held securely in the abdominal wall by a strip of aponeurosis that will not stretch and cannot come loose

from its attachments, because they are natural and have not been separated.

81. **Value of Electric Light in Treatment of Infections.**—Ochsner directs attention to the great value of electric light rays, especially because of their influence in controlling pain due to infection. He has used this method in seventy-eight cases of infection of the extremities, and invariably the pain has disappeared promptly. Sixty-one of these cases were infections of the upper extremity, and seventeen of the foot. Equally satisfactory results were obtained in the use of the electric light in treating peritonitis following abdominal sections for the relief of suppurating conditions such as appendiceal abscesses, perforated gallbladder, etc., also in tuberculous and gonorrheal joint infections, in carbuncles and furuncles. In case of roentgen-ray burns the light treatment causes a rapid improvement of the conditions.

84. **Bunion, Its Causes and Cure.**—Robinson claims that enlarged sesamoids are the cause of bunions. The two sesamoids which develop normally under the head of the first metatarsal bone enlarge and grow downward and outward toward the head of the second metatarsal, and as the plantar fascia is tough it resists the sesamoids and with each step pushes them upward and inward and causes the head of the metatarsal to give in the line of least resistance, which is upward and inward. Because there is no pressure inward on the proximal phalanx of the great toe, it is held firmly by the strong ligaments and gradually the head of the metatarsal is displaced inward. This turns the great toe outward toward the other toes until in may cases the head is almost completely dislocated from the articular surface of the phalanx. Roentgenograms show that this dislocation corresponds to the size of the sesamoids. Bunion occurs on top of the foot when the sesamoids are enlarged and point straight downward toward the sole of the foot. The tough plantar fascia forces the sesamoids upward against the head of the metatarsal so as to displace it perpendicularly upward and the phalanx being held firmly to the tendon is not displaced. This produces a bunion on top of the foot. The cure in both cases is the same, namely, removal of both sesamoids. By way of preventive surgery, Robinson advises the removal of both sesamoids as soon as the first symptoms of bunion are discovered.

86. **Operation for Femoral Hernia.**—The principle of Dowden's operation is the placing of a ball of fat or other tissue, bigger than the abdominal aspect of the femoral ring, and fixing the ball in situ, the ligated sac of the hernia being displaced above the ball. The result of this is that the greater the intra-abdominal pressure, the more this ball is forced against the femoral ring, this effectually closing it.

1. **Study of Kala-Azar.**—Pure subcultures of the flagellates of *Leishmania tropica* and of *L. donovani* were readily obtained by Cornwall and Menon by inoculating N N N tubes from the stomachs of infected bugs up to ten days from the date of the feed. No subcultures of the flagellates of *L. donovani* could be obtained from the rectal contents of bugs from three to thirty-three days after an infected feed. No subcultures could be obtained from the rectal contents when the infected bugs had fed on a normal rabbit in the interval. No resistant forms could be detected microscopically in the rectal contents of bugs infected with *L. donovani*. Neither leukocytes nor erythrocytes remain stranded in the bug's sucking tube after a feed. The authors suggest that kala-azar may perhaps be transmitted by the rupture of an infected bug on an excoriated skin, but proof is wanting.

4. **Blood of Cholera Patients.**—A new method of preparing urease from Soya beans and new methods of determining the percentage of inorganic phosphates and chlorids in the blood serum are described by Shorten. Studying the blood of cholera patients Shorten found that there is a definite increase in the urea content of the blood in all cases of cholera of more than a few hours' duration. In cases which recover, there is an increase to a maximum in a few days, and then a gradual decline to normal. In fatal cases of postcholeraic uremia a very high percentage may be reached before death. On the other hand, retention of urea would seem to have nothing to do with the symptoms of this so-called uremia. The figures for nonprotein nitrogen follow those for urea more or less closely. It would appear that an excess of nitrogenous metabolites in the blood is not responsible for the symptoms in these cases. The observations on the variations of the alkalinity of the blood confirm the previous work of Sir Leonard Rogers. The occurrence of phosphatic retention in these cases is definitely established. It corresponds in a general way to diminution in the alkalinity—a high phosphatic content being usually found with low alkalinity and vice versa. Postcholeraic uremia is a misnomer. The condition really is a retention acidosis, as shown by the diminished alkalinity, phosphatic retention, and peculiar type of dyspnea. The concomitant retention of urea and other nitrogenous metabolites does not appear to be of any importance, except in so far as it denotes abeyance of the functions of the kidneys. Improvement in treatment resolves itself into measures directed toward controlling phosphatic retention.

5. **Action of Liquor Calcis on Comma Vibrios.**—It would appear from Mukherji's bacteriologic experiments that liquor calcis is distinctly inimical to the growth of comma vibrios if used in sufficient quantity.

8. **Margosic Acid and Salts in Syphilis and Skin Diseases.**—After passing the oil derived from Nim seeds (Margosa tree) through various chemical processes, a chemist obtained margosic acid and sent Chatterji 4 ounces of a 15 per cent. alcoholic solution. Later, he prepared the calcium and zinc salts of this acid. These were found to be insoluble in water. Local application of them in powder, and as an ointment, prepared from them with petrolatum and lanolin, to syphilitic ulcers and tuberculous sinuses caused rapid healing. The ulcers showed a healthy healing margin after two or three applications. The chemist also prepared for Chatterji the sodium salt of the acid, sodium margosate. Intramuscular injections of this salt did not produce any toxic effects. Intravenous injections were followed by a sharp reactionary rise of temperature, but there was no other toxic effect. Investigations with the margosates show that along with their strong parasitotropic properties they have the advantage of possessing very low organotropic properties. The phenol co-efficient of the soluble salts of margosic acid has been determined to be only two. Laboratory experiments show, therefore, that the antibacterial or bactericidal property of the drug, is low, in vitro, but clinical evidence appears to show that this property is not inconsiderable in vivo. The Nim is a reputed remedy for skin affections and, in view of the parasitotropic properties of the margosates, they have been used in a number of cases of scabies, eczema and pemphigus with remarkably good results.

The margosates are strongly antiprotozoal in their action. A solution of 1 in 2,000 killed Paramecium instantly and a much weaker solution of 1 in 10,000 killed the flagellate Prowazekia. In the treatment of syphilis, clinical experience proved its value. Sodium margosate was given in solution, the doses varying from 0.01 to 0.325 gm., subcutaneously, intramuscularly or intravenously in the primary, secondary and tertiary stages of syphilis, also in parasyphilis and congenital syphilis. In the primary and secondary stages the initial lesion and secondary manifestations disappeared under its influence much more readily than in untreated cases. In the late secondary and tertiary stages the skin lesion, gummas, etc., soon subsided. A case of parasyphilis showed marked improvement. In congenital syphilis, the condylomas, ulcers, eye lesions, etc., yielded rapidly to treatment with the margosates. Incidentally Chatterji observed some aspects of the physiologic action of the drug. For example, it caused leukocytosis which was maintained for over a week after a single injection. It is not known how the margosates produce these results.

11. **Leprosy Treated with Sodium Gynecardate "A."**—This report is made by Muir after three months' treatment. A 3 per cent. solution of sodium gynecardate "A" in distilled water, with 1 per cent. of pure phenol and 1 per cent. of sodium citrate, was prepared, and sterilized by boiling in a flask immersed in another vessel containing water. Of this solution, from 0.5 c.c. up to 5 c.c. was given thrice weekly, intravenously. Tablets of the same drug were given by mouth, but it was not always found possible to give these regularly, and so far as could be judged the oral administration made little or no difference. The principle adopted was to begin with 0.5 c.c. and increase the dose by 0.5 c.c. each time, giving the injections thrice weekly. Anesthesia was present in all the patients. There were marked tubercular nodules in twenty cases. One patient after a few injections developed dysenteric diarrhea and the treatment had to be stopped. He, however, made some improvement, and the treatment is being resumed with care. Three patients, who had been ill, five, four and eighteen years, respectively, have entirely lost all traces of anesthesia and the nodular swelling which was found in the last of these has practically disappeared. The most rapid progress was recorded in the youngest patients and in those who had been ill for the shortest time; but this latter does not always hold, as the disease may advance more rapidly in some cases than in others. Many of the patients felt very weak at the end of the three months, but they were extremely cheerful. Muir has used leprolin in the treatment of leprosy for some years, and obtained improvement in many cases and the entire disappearance of anesthetic patches in a few initial cases. The original gynecardate of soda prepared under Sir L. Rogers' instructions gave better results than leprolin. Sodium gynecardate "A," however, has given vastly superior results to either of these.

Annales de Médecine, Paris

March-April, *1918*, **5**, No. *2*

15 *Soldier's Gastritis with Hyperchlorhydria. M. Loeper and G. Verpy.—p. *97*.
16 *Central Neurofibromatosis. G. Humbert and F. Naville.—p. 108.
17 *Wounds of Spine with Intact Dura. Guillain and Barré.—p. 115
18 Typhoid Lesions in Arachnoid. R. Lutembacher.—p. 148.
19 *French Sprochetosis. N. Fiessinger.—p. 156.
20 Paratyphoid with Epilepsy. Pagniez and Vallery-Radot.—p. *179*.
21 Spirochetoses. R. Dujarric de la Rivière.—p. 184.

15. **Soldier's Gastritis with Hyperchlorhydria.**—Loeper and Verpy have encountered seventy-two cases of this type among 135 cases of dyspepsia in soldiers. The symptoms indicate *actual gastritis*, the result of repeated functional hyperstimulation. Restriction to a nonirritating diet, milk, potatoes and sugar, aids in recuperation. Solutions of sugar are soothing, they induce by their concentration a mucous exudation, and they supply calories. The highly sweetened diet recommended in cases of gastric ulcer is particularly useful here, as it tends to reduce gastric secretion. Among the active measures, emptying the stomach and rinsing it with weak solutions of bicarbonate are effectual, also ingestion half an hour before meals of some alkaline solution, phosphates, sulphates, with *sodium citrate.* Also a suspension of bismuth carbonate taken fasting.

16. **Central Neurofibromatosis.**—Bilateral central deafness is common with this disease; Henschen declares that there are always two neuroma on the eighth pair of nerves. This was the case in the sixteen instances he has compiled, but in the family here described only the father presents this bilateral deafness. The two sons are deaf only on one side. One son of 32 has a neurofibroma on the optic nerve and retina, visible with the ophthalmoscope since the age of 7. The brother died at 18 and the father at 31.

17. **Paraplegia After Wounds of Spine with Intact Dura.**—Fifteen cases are described of organic paraplegia following a war wound of the spine, but in which the dura was found intact. The points which distinguish between the set of symptoms from total section of the cord and those from a focal lesion are an extensive plantar skin reflex on both or even on one side, conservation of sensibility over an area, even if quite limited, and pain when the thigh is flexed at the hip. Lumbar puncture shows when there is subarachnoidal hemorrhage.

19. **French Spirochetosis.**—The clinical picture may resemble that of catarrhal jaundice or of meningitis with myalgia and nausea, the symptoms subsiding after lumbar puncture, or it may appear as war nephritis, trench foot, or as an infectious disease of unknown nature. A. Pettit was the first to insist that the spirochete involved is not identical with Inada's icterohemorrhagic spirochete in Japan. The spirocheturia with the latter appears only after defervescence, not until after the first week, while in the French spirochetosis, spirocheturia was pronounced from the first to the fourth day in the Lorient epidemic. In the sporadic cases the spirocheturia is tardy. The French spirochete is also longer, with more twists, and guinea-pigs seem absolutely immune to it. The serum of patients contains no immunisins against the Japanese spirochete. The French spirochetosis is essentially polymorphous, and includes undoubtedly a number of pyrexias of hitherto unknown origin. It is possible that trench foot belongs in another category, but at present it seems to fit into this elastic frame.

Archives Médicales Belges, Paris

26 *Disability with Mutilation of Face and Jaws. F. Watry.—p. 583.
27 Psychogenous Motor Psychoses. M. Molhant.—p. 591.

24. **Pneumatic Mobilization of Stiff Joints.**—Eighteen illustrations show the apparatus and the method of use for stiff joints. The principle is the application of pressure by a rubber bag alternately inflated and collapsed by air from a pump worked by an electric motor. The motor is connected with iron piping which has manifold outlets with pinch-cocks at regular intervals, the inflatable bags being connected with these branching tubes. All are inflated simultaneously with the compressed air, for about a minute, and the joints thus get a succession of small efforts at mobilization which aggregate in time enough force to correct the ankylosis. This principle was first applied for massage. It is accomplishing results in the line of mobilization beyond the highest anticipations, it is said, not only for knees, wrists and fingers but for constriction of the jaws, and for the elbow, talipes varus and equinus, etc. Continuous traction accomplishes the same purpose, but the soft parts are rendered anemic in the process, blood and lymph are expelled, and conditions are not favorable for recuperation of function. With the rapid alternating application of force and its release, the soft parts undergo a constant massage as the muscles repeatedly stretch and retract. One unexpected advantage of the method is that it shows up factitious ankylosis. The sittings are given every day or twice a day.

25. **Visual Acuity in Soldiers.**—Rasquin discusses from the military standpoint the evaluation of the disability from reduction of visual acuity.

26. **War Wounds of Jaws and Face.**—Watry discusses the mutilations of jaws and face from the same standpoint of military disability and reduction of the earning capacity.

Bulletin de l'Académie de Médecine, Paris

July 23, 1918, **80**, No. 29

28 *Arteriovenous Aneurysm. L. Sencert.—p. 114.
29 *Hemoptysis after War Wounds of Chest. Courtois-Suffit.—p. 116.

28. **Subclavian Arteriovenous Aneurysm.**—Sencert reports the complete functional recovery after resection of an arteriovenous aneurysm in the subclavian vessels. In order to reach it, he temporarily disarticulated the clavicle.

29. **Hemoptysis After War Wounds of Chest.**—Courtois-Suffit refers to the hemorrhages which occur after a long interval and display a tendency to recurrence after a war wound of the chest. In one of the four cases summarized, the interval was thirty months. Nothing can be found in any of the cases suspicious of tuberculosis, and the recurring hemoptysis is not accompanied by any impairment in the general health. Tuberculosis is proving extremely rare as a complication of war wounds of the chest. He cites seven other hospital physicians, besides himself, who have never encountered an instance of it. The war wound, especially when a foreign body is left in the tissues, may keep up a latent inflammatory process which may bleed at times.

Bulletins de la Société Médicale des Hôpitaux de Paris

May 10, 1918, **42**, No. 16

30 *Gangrene of Uvula in Purpura. L. Galliard.—p. 435.
31 *Lethargic Encephalitis. Lortat-Jacob and Hallez.—p. 439.
32 *Meningitis. M. Beauchant, Baudoin and Dubois.—p. 444.
33 *Trauma and Tuberculosis. A. Lemierre and Lantuéjoul.—p. 449.

30. **Gangrene in Purpura.**—The purpura was relatively mild in the man of 49 but gangrene developed in the uvula and it sloughed off leaving only a stub. Bleeding from the gums had been the first symptom and the uvula was swollen. The physician ordered local treatment with diluted hydrogen peroxid. Netter has reported the cultivation of what seemed to be meningococci in the vesicles in a case of purpura in an infant, as also in several cases in adults, and others have reported gangrene in meningococcus purpuras. Some of the patients recovered without having been given serotherapy. In Elliot and Kaye's case, both feet had to be amputated.

31. **Lethargic Encephalitis.**—The woman of 49 was brought to the hospital because for a week she had not been able to keep awake, and she complained of feeling tired all the time, and there was ptosis of the eyelids. Three weeks before she had suffered for a week from severe headache. The lethargy, the tendency to catatonia and loss of pupil reflex to light gradually subsided in this order. The somnolency in this and similar cases seems to be a symptom of exhaustion, a phenomenon comparable to what occurs in the motor system in bulbar myasthenia.

32. **Puncture of Ventricles in Meningitis.**—The young aviator developed suddenly acute meningitis with violent delirium; serotherapy was pushed for a week without apparent benefit. Then, on account of the aggravation of the symptoms notwithstanding the specific serotherapy, both lateral ventricles were punctured, followed by injection of 10 c.c. of the specific serum in one ventricle and 5 c.c. in the other. Meningococci were found in the 15 c.c. of fluid aspirated from the first ventricle punctured. By the next day improvement was pronounced, and it continued without further setbacks except a subcutaneous abscess at the point where the scalp had been trephined for each puncture of the ventricle. Pure cultures of meningococci were derived from the pus, but recovery continued undisturbed. The facility with which the ventricles can be punctured always astonishes those who try it. In the case reported a fixation abscess had been induced, as this is deemed useful in grave meningitis, and it may have contributed to the favorable outcome.

33. **Traumatism and Tuberculosis.**—In two of the three cases of war wounds of the chest reported, a latent tuberculous process flared up, but in the third case a contusion of the chest was followed by development of acute pleurotuberculosis, almost at once, which seemed to be primary.

39 *Bimanual Percussion. O. Peyret.—p. 387.
40 Febrile Bilious Hemoglobinuria. F. Roux.—p. 390.

34. **Access to the Mediastinum and Neck.**—Le Fort analyzes the different methods that have been proposed for access to the cervicomediastinal space, at the base of the neck, and advocates what he calls the sternocleidocostal flap. The skin is incised along the median line for 10 or 12 cm. to the first intercostal space, and then at right angles to the first incision for 12 or 14 cm. along the intercostal space to the deltoid, thus forming an L. His illustrations show how this avoids mutilation while it affords ample access. By this means he was able to remove without mishap a shrapnel ball just above and back of the aorta which, for sixteen months, one surgeon after another had refused to remove. Except for temporary incision of the sternum—which is a spongy bone and consolidation afterward is rapid and sure—no bone, vessel, nerve or important muscle is injured in the least, the clavicle and its articulation and the sternomastoid being unmolested, while it gives ample access to the organs at the base of the neck, the entire upper mediastinum and the apex of the lung. The integral repair of the chest wall requires only suture of the intercostal space, of the pectoralis and the fibro-aponeurotic plane.

37. **Acute Osteomyelitis of the Spine.**—Luzoir summarizes some recent cases that have been published, emphasizing the vital importance of an early diagnosis. Kirmisson called attention in 1909 to the characteristic oblong shape of the swelling over the inflamed vertebrae, almost spindle shaped. In one of his four cases the swelling along the side of the spine reached from the scapula to the crest of the ilium. Another symptom is the manifest collateral circulation in the region. The temperature is subfebrile, and puncture brings pus with usually the *Staphylococcus aureus* in pure culture. The absence of any tendency to curvature of the spine and the presence of some focus of infection elsewhere aid in differentiating the acute osteomyelitis. In one of the cases cited the spinous processes of the eleventh and twelfth dorsal vertebrae were found denuded, with four perforations in the sacrolumbar aponeurosis. The focus was cleared out and cauterized with phenol neutralized at once with alcohol, and in less than two months the lesion had completely healed. In other cases a subacute, almost chronic course would suggest tuberculosis if it were not for the long outline which is in such contrast to the round Pott's lesion. In other cases the symptoms of septicemia predominate, suggesting typhoid or meningitis. In one such case the young man was being treated for typhoid until the casual discovery of the swelling in the lumbar region. The operation then came too late to save him. Only thorough examination in all cases of supposed typhoid would avert blunders of this kind. In a more recent case the grave general condition and signs of meningeal irritation pointed to meningitis, but the finding of staphylococci in the spinal fluid led to more careful examination of the spine and discovery of the acute osteomyelitis, with recovery after draining the spinal canal. The first symptoms in this case had been acute retention of urine, without discoverable cause, and pains in the spine.

38. **Constipation in Men on Active Service.**—The lack of fresh vegetables in the soldiers' rations at the front entails constipation. It may be simple or spastic, or of the atonic or toxic type, or with inflammation. The gravity of the latter groups shows that constipation should never be neglected, to ward off these more serious developments. In prophylaxis, efforts should be made to supply the soldiers with vegetables and fruits, fresh or dried. Labbé advises in the toxic form disinfection of the bowels by means of cultures of lactic and paralactic bacilli, calomel, benzonaphthol and

naphthol, used alternately. Liver extracts and bile extracts are useful to stimulate the liver and bowel functioning.

39. **Bimanual Percussion.**—Peyret gives illustrations of this means of determining the dulness characteristic of pulmonary tuberculosis. The two hands are not applied opposite each other but on radii from the common center being percussed. The palms are applied flat, one over the anterior margin of the clavicle at the middle of a line joining the bifurcation of the sternum with the outer point of the acromion above the head of the humerus. The other hand is placed on the spine of the scapula. A line is drawn to connect these points, passing over the shoulder and extending a few inches beyond them. This he calls the *ligne directrice* as the percussion is applied along this line. He devotes nearly nine columns to describing the exact technic and the information to be derived from the percussion.

Revue Médicale de la Suisse Romande, Geneva

July, 1918, **38**, No. 7

41 *Pneumococcemia in Children. D'Espine and Reh.—p. 413; Turrettini.—p. 436.
42 *Mechanism of Conjugated Deviation of Eyes and Rotation of Head in Hemiplegia. L. Bard.—p. 423.
43 Carbonated Baths for Intermittent Claudication. E. de La Harpe.—p. 429.
44 *Imperforate Anus. Veyrassat.—p. 433.

41. **Pneumococcemia in Children.**—D'Espine and Reh state that the mortality was 3.7 per cent. in 374 cases of pneumonia in children in the seven years ending with 1917. Then came a series of 32 cases with 9 per cent. mortality. In one family there were 2 cases with early fatal empyema, although there did not seem to be mixed infection. In 9 cases there was pneumococcus meningitis with only one recovery. Netter has reported 17 cases of meningococcus meningitis with tardy pneumococcus invasion, all terminating fatally notwithstanding serotherapy. But D'Espine here relates a case of similar mixed infection with recovery under antimeningococcus serum treatment. One of the children had a pneumococcus sore throat and the pneumococci were found in the blood, but prompt recovery followed. A case is also described of febrile pneumococcemia in a girl of 3 without any manifest localization of the infection. The pneumococci were cultivated from the blood repeatedly during nearly a month, the fever keeping up with a typhoidal condition for three weeks; under six intravenous injections of a silver preparation the temperature finally dropped to normal.

Turrettini reports the case of an infant less than 5 months old who developed pneumonia, and the pneumococcus was found in the blood on repeated examinations during the following six months, with final complete recovery. The child increased in weight during the 180 days of its septicemia and occasional febrile temperature. The autovaccine from the persisting septicemia evidently attenuated the virulence of the pneumococci to such an extent that the growth of the child was scarcely interfered with.

42. **Rotation of Head and Eyes with Hemiplegia.**—Bard explains how the loss of the gyratory reflexes on the paralyzed side induces an automatic predominance of the gyrations in a determined direction, a sensorial hemi-agyria, as he calls it.

44. **Imperforate Anus.**—The rectum opened in the vagina but this was not discovered by any one, it is said, till the babe was 6 months old and wasting away from abdominal disturbances and general debility. The transplantation of the anus to the perineum was peculiarly difficult in such a young and restless child, but the operation was a perfect success. The child is now 5 years old and free from both retention and incontinence. After the operation the mother was instructed to dilate the anus occasionally with her finger.

49 The Prevailing Three-Day Fever Epidemic. G. Sampietro.—p. 300.

45. **Passage of Rabies Through Placenta to Fetus.**—Lanfranchi and Lenzi report the case of a gravid bitch that had succumbed to rabies at term. Rabbits inoculated with medulla tissue from the mother and from the fetuses all died with symptoms of rabies.

47. **One-Sided Diet, Pellagra and Scurvy.**—Volpino has been studying deficiency diseases for years, and here describes his extensive experimental research and compares the results with those that have been reported by others. Among the experiences reported was the finding that pellagrins respond with a pronounced local and general reaction to injection of extracts of spoiled and sound maize. Similar series reported by others bring the total to 136 positive and eleven dubious or negative responses in 147 pellagrins, while positive responses were obtained only in thirty-three of 130 nonpellagrins. He regards these findings as testifying to sensitization of the pellagrins. The article is to be continued.

48. **Immunity of Fowls to Anthrax.**—Sarti inoculated hens and pigeons with the anthrax virus subcutaneously, by the vein or in the anterior chamber. The fowls proved to be immune even to large doses of the virus, but a few of the pigeons developed anthrax septicemia. Study of the blood and other factors involved shows that several factors evidently cooperate in this natural immunity. The ferments in the blood serum sensitize the micro-organisms so that they fall easy prey to the phagocytes. Fasting reduces the defensive forces and may practically suspend the immunity.

50 *Roentgen Examination of Child's Chest. F. P. Sgobbo.—p. 385.
51 *Vaccine Prophylaxis of Scarlet Fever. G. Caronia.—p. 406.
52 *Diphtheria Bacilli Carriers. S. Cannata.—p. 414.

50. **Roentgen Examination of Chest in Children of Different Ages.**—Sgobbo examined eighteen boys and twelve girls from families of working men; only 20 per cent., including the supposedly healthy, gave normal findings in the lymphatic glands of the mediastinum and lung. In those with pathologic antecedents of any kind, the findings were always positive. It is possible that some of the glandular lesions may have been the result of other than tuberculous processes.

51. **Vaccine Prophylaxis of Scarlet Fever.**—Caronia and Di Cristina's previous work in this line has been duly chronicled in these columns. Di Cristina makes the vaccine from an extract of the scales, an antigen having been found in them which seems to be able to confer permanent immunity. He makes the vaccine by dissolving out the antibodies, soaking the scales in serum from convalescents. Subcutaneous injection of this vaccine induces the production of a specific amboceptor for the alcoholic extract of the desquamated scales. This confirmed that the reaction observed is not a simple reaction of the lipoids contained in the scales, but is also due to the presence of antigens in the true sense of the word. Children from 2 to 9 years old, treated with the vaccine until the immunity reaction appeared, in close contact with scarlet fever patients or with peeling convalescents, never developed scarlet fever. These experiences substantiate that the branny scales are the last stronghold of the causal germs in the organism. They further demonstrate the feasibility of the biologic differential test by this means, and also of effectual prophylaxis and possibly of treatment.

The Clinica Pediatrica at Naples consists merely of two large contiguous halls, each containing ten beds. One of these wards is given up to infants, the other to the larger children. There are no provisions for isolation, and not even for observation, so that when a recent arrival proved to have scarlet fever, its epidemic spread seemed inevitable. One of the children in the ward soon presented symptoms of the disease, and all the other children in the ward were injected with the scale vaccine. He also injected the vaccine in some children in private families when one had developed scarlet fever. None of the twenty-three children thus treated developed the disease, and only two, both feeble infants under 2 years old, presented a few symptoms indicating an abortive type of infection. Possibly these infants had been injected after infection was already under way. The immunization of the vaccinated children was rendered apparent by the deviation of complement test. He injected 1 c.c. of the vaccine on three alternate or consecutive days. The two primary cases of scarlet fever remained in the ward throughout their disease and desquamation, but no other cases developed.

52. **Diphtheria Bacilli Carriers.**—Cannata compares a number of recent publications on this subject. He had to stamp out an incipient epidemic of diphtheria in a battalion in active service. As bacteriologic examination of the 1,200 men was out of the question under the circumstances, he swabbed the pharyngeal mucosa of all the men with iodized glycerin, and no further cases developed. Smears from the throat of 250 later showed the bacilli in only one case. Schiøtz noticed that children with a staphylococcus sore throat placed by mistake in the diphtheria ward never contracted diphtheria. He accepted this as a suggestion to apply cultures of the staphylococcus in local treatment of the pharynx, and has reported excellent results. Ten other writers have published favorable results confirming the efficacy of this antagonistic bacterial treatment. They spray the nose and nasopharynx with eighteen or twenty-four hour bouillon cultures of the *Staphylococcus aureus*, and only a few have reported disappointing results. Lactic acid bacilli; pyocyanase; a diphtheria vaccine, and desiccated horse serum previously treated with cultures of diphtheria bacilli have also been used. With the latter method no further bacilli were found after twenty-four hours in the thirty-five cases tested.

57 *Joint Manifestations of Tardy Inherited Syphilis. M. R. Castex and R. Denis.—p. 37. Commenced in No. 1, p. 1.
58 *Rectal Medication in Syphilis. C. A. Castaño.—p. 42.
59 Tetanus and Industrial Accident Insurance. L. Bard.—p. 42.

57. **Joint Manifestations of Tardy Inherited Syphilis.**—Castex and Denis report in detail a large number of cases which demonstrate that tardy inherited syphilis is able to induce a clinical picture deceptively resembling that of acute polyarticular rheumatism. If the causal syphilis is overlooked, these cases may degenerate into chronic and absolutely incurable conditions, simulating ordinary chronic rheumatism. In differentiating the syphilitic origin, other members of the family should be examined for stigmata of syphilis, and the personal, familial and inherited antecedents investigated with minute care. In any event, they advise vigorous treatment as for syphilis, as it can never do harm while it is the only means to ward off irreparable lesions. The most common forms of the tardy joint manifestations of inherited syphilis simulate white swelling and hydrarthrosis, usually affecting the knee or hip joint. They may subside completely under specific treatment in the early stages. The mode of onset and the progress are important points in differentiation, as also the exclusion of tuberculosis and rheumatism. The long serial article is profusely illustrated.

58. **Rectal Treatment of Syphilis.**—Castaño states that when circumstances render injections impracticable, he has obtained excellent results by administering mercurial treatment by way of the rectum. In his several years of experience with this technic he has never had any inconveniences from it. Farini of Buenos Aires has even administered both mercury and arsphenamin by this route, with surprisingly good results. In some of Castaño's cases the patients developed stomatitis in a few days, confirming the absorption of the mercury. He administers it in a coco butter suppository, one on retiring, suspending the treatment for three or four weeks after the suppositories have been administered for twenty days, then resuming the treatment again. When the patient has bad veins, he prefers to administer neo-arsphenamin by the rectum, instilling it slowly and keeping the patient reclining for a time. He uses the same doses with this as for intravenous injection.

64 Anteversion and Retroversion of Pelvis. E. A. Boero.—p. 172.
65 Technic for Classic Cesarean Section. N. Fernandez.—p. 175.

60. **Acute Postpartum Dilatation of the Stomach.**—Iribarne is convinced that this is of more frequent occurrence than generally supposed, but often escapes recognition. P. Ramos could find only seventeen cases on record during the nine years that had elapsed since Audibert reported the first case in 1907, but during the two years since, six cases have been encountered in Argentina alone. Iribarne reports an exceptionally severe case in a secundipara. The delivery of a normal child had been spontaneous and expeditious, and the general condition was good, but about twenty minutes after expulsion of the after-birth there was slight hemorrhage. The midwife injected ergot and camphorated oil, and massaged the uterus, but the slight hemorrhage still persisted. By the end of the hour the pulse was fast and small, and the woman complained of feeling suffocated, and there was much pain. The pallor was extreme, but the uterus had contracted well and the hemorrhage had practically ceased. Iribarne injected saline subcutaneously and by the vein, and injected a pituitary extract. The general condition was growing rapidly worse, the pain and sense of oppression intense, the pulse 150 and almost imperceptible, although the conditions in the genital sphere were physiologic. The woman's expression of distress increased, the pulse became 160 and 170, and then became totally imperceptible. There was no vomiting or thirst, but the bulging of the stomach confirmed the suspicion of acute dilatation of the stomach, and on turning the woman into the prone position, with the mouth open, there was a rush of gases from the stomach and rectum, followed by vomiting and great relief. But the pulse was still imperceptible, and the woman was chilly. Pituitary extract was injected anew, hoping to act on the musculature of the stomach and on the heart. The woman felt relieved, but was unable to lie prone and was turned on her back; oxygen was administered, with saline, epinephrin, caffein and strychnin, while hot water bottles were packed around her and she was rubbed with alcohol. Then the oppression and suffocation returned, as severe as before, but were relieved again by making the woman lie prone. An attempt at lavage of the stomach was then made, but the woman stopped breathing as the tube was introduced into the esophagus, and her eyes rolled up. The tube was withdrawn and ether was injected, and the skin rubbed vigorously, and she revived but the condition was still very grave. Pituitary extract was given and the woman turned on her stomach, which was followed by belching of gases and vomiting. From 10 p. m. to 2 a. m. they were thus working over her, the pulse absolutely imperceptible throughout. Then the pulse began to be felt and by 2:30 the condition was no longer alarming, and recovery proceeded although there was a tendency to gastric intolerance and lassitude for some weeks.

Iribarne explains the mechanism of the arteriomesenteric occlusion which accompanies the dilatation of the stomach, and the cessation of the occlusion in the prone position. The woman should be turned to this position on the slightest suspicion of acute dilatation of the stomach. It does no harm in any event, whatever is the matter, while it is a life-saving measure with true arteriomesenteric occlusion of this kind.

61. **Treatment of Inaccessible Vesicovaginal Fistulas.**—The transvesical operation is the most logical because it goes direct to the fistula; it is the easiest technic, and the most effectual. Three cases are described which illustrate the advantages of this method.

63. **Embryotomy.**—Beruti's modified instrument consists of a curving spiral spring that is pushed through a stiff

cannula. The spiral spring curves of itself around the fetal neck, and the end can be drawn down and attached to a Gigli wire saw. The saw is drawn up by pulling the flexible wire spiral spring back into the cannula.

Revista de la Asociacion Medica Argentina, Buenos Aires

April, 1918, **28**, No. 161

66 *Pancreatic Infantilism. R. A. Bullrich.—p. 303.
67 *Cyst in the Prostate. E. Castaño.—p. 317.
68 Syphilis in Medical Diagnosis. R. P. Escalier.—p. 325.

70 Torticollis Tic. T. Martini and J. J. Berterini.—p. 349.
71 Mercurial Treatment of Children. J. C. Navarro.—p. 360.

66. **Pancreatic Infantilism.**—Bullrich reports a typical case of Byrom Bramwell's pancreatic infantilism, with the necropsy findings. The case was distinguished further by the patient's being a diabetic. Necropsy revealed that the trouble was not in the pancreas so much as in the thyroid and pituitary body. There were lesions in the pancreas but they were insignificant compared to those in the thyroid and pituitary body. The case was one therefore of pluriglandular derangement. He had been normal and well grown till about the age of 11 when he began to grow thin and at 16 had pronounced diabetes mellitus. Then came eight months of rebellious diarrhea. At the age of 20 he was intelligent but was only about 4 feet tall and weighed only 21 kg. The skin was very dry and wrinkled like that of an old man, and the urine contained from 38 to 45 per thousand sugar. The stools showed signs of pancreas deficiency. Death occurred suddenly in an epileptiform convulsion, with nothing to suggest diabetic acidosis.

67. **Prostatic Cysts.**—In the two cases which Castaño has encountered, the cyst was in carcinomatous degeneration. The one patient whose case is described with illustrations has been in good health during the nine months or more since the prostatectomy. Prophylactic radium therapy was applied systematically during the first six months.

Revista de Medicina y Cirugia, Havana

June 25, 1918, **23**, No. 12

72 *The Mammary Fluid in the Newly Born. J. F. Arteaga.—p. 323.

72. **The Mammary Fluid in the Newly Born.**—Arteaga investigated on fifty-two infants the fluid that could be expressed from the mammary glands, just after birth up to twelve days or nineteen days. The findings in 97 per cent. indicated that the fluid was of the nature of a secretion, a physiologic phenomenon, independent of sex, breast feeding, and the obstetric and pathologic antecedents of the mother. In some the secretion kept up for from twelve to sixty-two days, with an average of forty-three days. In another child it kept up for 128 days.

75 Gastro-Intestinal Resections. Chavez and Yaniz.—p. 296.
76 Solid Tumors of Spermatic Cord. G. Pujadas.—p. 299.

74. **Mixed Infections.**—Figueras reports a case of diphtheria in which streptococci were found in the smears, as well as diphtheria bacilli. The child was treated with both diphtheria antitoxin and an antistreptococcus serum, and also with serum from the renal vein of a goat as the condition was grave and the anuria persisted. Improvement was evident in a few hours, and under renewed injection of the goat serum and antistreptococcus serum the child recovered, the symptoms on the part of kidneys and myocardium gradually subsiding. There were no signs of serum sickness although 17,000 units of the antistreptococcus serum had been given besides the goat serum and the antitoxin. This child's brother had pure diphtheria at the same time, and was left a carrier until the tonsils were removed.

Revista Medica del Rosario, Argentina

July, 1918, **8**, No. 3

77 *Bacteriology of Blood in Puerperal Fever. E. Mazzini.—p. 171.
78 *Syphilitic Diabetes Insipidus. T. Fracassi.—p. 197.
79 *Visit to Lyons Maternity. J. B. Abalos.—p. 208.
80 *Brain Tumor in Girl of Twelve. C. Muniagurria.—p. 221.

77. **Bacteriologic Examination of the Blood in Puerperal Fever.**—Mazzini charts the bacteriologic findings in sixteen cases of puerperal fever, and emphasizes that clinical examination alone is not enough for the diagnosis and prognosis in this disease. Bacteriologic examination is indispensable not only for the blood but also for the lochia. The discovery of virulent bacteria and their increasing numbers on repeated examinations point to a fatal outcome. On the other hand, the diagnosis and prognosis cannot be based exclusively on negative bacteriologic findings. In his series, staphylococci or streptococci were found in the blood in 30 per cent. and half of these cases terminated fatally. In one of two cases with streptococci in the blood, the general condition was very grave but the numbers of streptococci grew constantly less and the woman recovered. The other seemed to have a mild case but the increasing numbers of streptococci in the blood warned of the impending fatal termination. The bacteriologic findings were positive in six of fifteen cases; typhoid bacilli were found in one fatal case, and, associated with staphylococci, in one woman who recovered. Jaundice was present in two cases with hemolytic streptococci but one of the two women recovered. He cites literature on the subject, mentioning Veit's experience that the prognosis was less unfavorable when gonococci were found with the streptococci or with colon bacilli.

78. **Syphilitic Diabetes Insipidus.**—Fracassi reviews the theories of defective or excessive pituitary functioning as the cause of diabetes insipidus, and the theories based on hormones and trophic centers. They all seem to accept a single origin for all forms of diabetes insipidus, namely, some organic or functional disturbance in the pituitary body or polyuric brain centers. In a case described, the young man within three months developed polyuria up to 15 liters in the twenty-four hours. He had had three attacks of gonorrhea during the last seven years and an indurated chancre during the sixth year, but there had been no secondary manifestations. In the last month there had been lightning pains in the legs and quite recently a little fever. All the symptoms subsided under mercurial treatment, the amount of urine dropping from 10,000 to 6,500 c.c. in the course of eight daily intravenous mercurial injections. By the twentieth injection the total output of urine was only 2,000 c.c. Muniagurria has published a similar case of cure of diabetes insipidus under specific treatment.

79. **Obstetric Technical Points.**—Abalos gives an illustrated description of his visit to the Clinique Obstétricale in charge of Fabre at Lyons. One pavillion is devoted to "girl-mothers" and abortion cases. The morbidity has shown great improvement since the pregnant are given only douche baths, after the first all-over cleansing bath. Fabre believes in "mathematical obstetrics." He has found that the uterus grows each month 4 cm. By the end of the fourth month it should reach 14 cm. above the pubis, and with approaching term it should reach to about 32 cm. By weekly measurements, this normal upward progress can be traced. If it does not occur, the death of the fetus is probable. If the uterus reaches higher than 32 cm., hydramnios or twin gestation or contracted pelvis should be suspected. Fabre determines the measurements of the pelvis with a roentgen tube 50 cm. above or 20 cm. below the level of the pubis, the woman lying prone on a barred frame on which the shadow of the bones is outlined, each square representing 1 cm., the squares drawn as by Mercator's projection. Three illustrations show the system and the precision of the measurements thus obtained. Another illustration shows Fabre's dynamometer used in connection with the forceps to gage the force applied. A description is also given of a pneumatic device, strapped around the waist, to record the contractions of the uterus.

Fabre insists on isolation for every parturient harboring the streptococcus. He regards the turpentine fixation abscess as the sovereign remedy for puerperal fever. It acts, he thinks, by inducing the production of antibodies from the irritation of the tissues, and it has besides a direct and elective action on the streptococcus. He uses turpentine also in prophylactic injections into the uterus in a 5 per thousand solution; after delivery, in a 10 per cent thousand solution. For cauterizing, he uses a 10 or 20 per cent. suspension in oil. For the fixation abscess, from 1 to 5 c.c. of pure turpentine. For artificial serum, he dissolves 1 gm. of turpentine in 1 gm. of alcohol and pours it into 200 gm. of artificial serum. The mortality has been reduced by 10 per cent. since this turpentine treatment has been systematically used. The total mortality in the ten years ending with 1913 has been 0.47 per cent. in 11,582 obstetric cases, and puerperal infection was responsible for less than half of this. The total morbidity dropped from 21.7 to 11.1 per cent. between 1906 and 1913.

80. **Brain Tumor.**—Three months of intense headache and vomiting with slight paresis of the arm in a girl of 12 were explained by an echinococcus cyst in the parietal lobe, invading the lateral ventricle. There was no eosinophilia.

82. **Systematized Prophylaxis of Tuberculosis.**—This extensive article gives numerous statistical tables of the death rate from tuberculosis in the different districts throughout Argentina, classified by trades and professions and compared with other countries. On this basis are outlined the measures that are proposed in prophylaxis.

84. **Precipitation Test for Nicotin and Other Alkaloids.**—Sanchez' reagent is a sulphomolybdate. It is exceptionally sensitive and has a number of advantages, he says, over other reagents for testing organic bases, especially in dosage of nicotin in tobacco and in extracts. The technic is simple and is described in detail.

86. **Treatment of Varicocele.**—The anatomic and clinical cure is realized by exposing the left anterior spermatic vessels and severing all the spermatic veins in this bunch between ligatures. The return circulation is thus diverted to the posterior vessels and epigastric vein, a tributary of the external iliac. The method has been applied only in three clinical cases to date.

88 *Epigastric Hernia plus Duodenal Ulcer. L. Urrutia.—p. 565.

88. **Epigastric Hernia Plus Double Duodenal Ulcer.**—Urrutia adds another to the list of cases on record in which an epigastric hernia was accompanied by ulceration in the digestive tract below. There were two ulcers in the duodenum, and each had bored through the wall. The perforation of each at a ten months' interval had induced a severe set of symptoms, but they had subsided spontaneously each time, the opening having evidently become obstructed after the acute phase was past. Conditions were corrected by resecting the segment of bowel involved and a gastro-enterostomy.

92 Retention of Nitrogen and Constant of Ambard in Inhabitants of Tropics. C. D. de Langen.—p. 36.

91. **Cholesterol Metabolism in the Tropics.**—De Langen discusses the pathology of races, particularly in regard to cholesterol metabolism. He investigated the latter in natives of Java, having been impressed by the rarity of gallstone cases at the polyclinic and surgical clinic in his charge. He found only one case on the records among the 15,000 patients at the hospital and this was not a native of the East Indies, while not a single instance was encountered among the 40,000 outpatients. The hospital at Sourabaja reports only seven cases among 67,500 inmates and outpatients. The figures from Semarang are eight cases in 47,000. In 1914, throughout the whole of Java, three cases of gallstones were recorded among the 58,021 hospital and outpatients. The cholesterol content of the blood of the natives is exceptionally low. This fact suggests a causal connection and disproves the theory that infection or stagnation is the prime factor in cholelithiasis. This assumption is the more plausible as the natives of the East Indies are subject to infections of the liver and biliary passages, and pregnancies there do not differ from pregnancies in other countries where gallstones are common. The few gallstones found in Java are usually of the rare pigmented type, such as is found with hemolytic jaundice. Pruritus seems also to be exceptionally rare among the natives, which in turn may be explained by the low cholesterol content of the blood. Diabetes and chronic nephritis, with which hypercholesterolemia is often associated, are likewise rare in Java. In conclusion de Langen tentatively recalls that beriberi is a disease locating in the nervous system—which is the most lipoid-rich tissue in the body—and hence study of beriberi may yet reveal that the vague notion of vitamins will merge into the problem of lipoid metabolism. Certain data he has accumulated sustain this hypothesis, and it is attractive further from a therapeutic point of view. *Chercher la physiologie c'est éclairer la pathologie.* The article is in parallel columns of Dutch and English.

98 *Diaphragmatic Hernia. V. Schaldemose.—p. 849.

July 3, 1918, **61**, No. 27

99 *Operation for Diaphragmatic Hernia. A. Helsted.—p. 881; Roentgen Findings. H. J. Panner.—p. 890.

98. **Suture for Diaphragmatic Hernia.** — Schaldemose remarks that a large proportion of diaphragmatic hernias cause no appreciable symptoms of any kind. When symptoms do develop they may be of the most diverse nature, depending on the organs which are most affected by pressure or by strangulation. Operative measures are the only treatment, and by way of the thorax seems the preferable route. It is difficult if not impossible to reduce the hernia from below and suture the opening.

99. **Diaphragmatic Hernia.**—Helsted's patient was a robust young man; a fall in getting out of a vehicle and a contusion of the neck not long after may have contributed to the hernia. The symptoms were those of periodically recurring partial incarceration of the stomach, with displacement of the heart and compression of the lung. The pains radiating to the left shoulder and down the outer side of the arm, plus the roentgen findings, differentiated the hernia. The roentgenograms all show the high curving convex line reaching, like a rainbow, from the median shadow to the left thorax wall. This line represents the air bubble of the stomach. Roentgenoscopy showed that this line moved up and down, synchronous with the movements of the right diaphragm, both in time and direction, although more sluggishly. He operated through the thorax with complete success. The suturing of the diaphragm was difficult on account of its constant movements. In another case of the kind he would try blocking the phrenic nerve on that side; this has been found effectual in keeping that half of the diaphragm quiet for several hours at a time. In the cases on record, catgut was used to suture the diaphragm, but he did not dare to trust to it and used fine silk, doubled. Five months later nothing abnormal can be discovered objectively, but the young man complains of palpitations and pain in the left chest, and inability to sleep lying down.

99. **Roentgen Findings with Diaphragmatic Hernia.**—Panner examined with the roentgen rays the two cases reported in the preceding two abstracts, and also a third case elsewhere. When several viscera are involved in the hernia, there may be several rainbow-like lines cast by the rounding tops of the air bubble in the different organs. The incurvation of the sides of the stomach—where it is grasped by the diaphragm—is also instructive. In the discussion that followed these three reports, read at a meeting of the Danish Surgical Association, Bartels described the conditions found in some cases in which necropsy had revealed an unsuspected diaphragmatic hernia. In one of the cases the sudden symptoms had suggested perforation of a gastric ulcer, but the roentgenoscopy findings seemed to indicate left pneumothorax. The lung cast scarcely any shadow on the left side, and a horizontal shadow seemed to indicate an effusion. The heart was displaced upward. The roentgen picture was typical for pneumothorax, except for the upward convex line arching across, but this was so indistinct in the roentgenogram that it was overlooked. The young man had been in the hospital for ten days when he complained of sudden intense pain in the chest, and died within a few minutes. Necropsy showed a hole in the diaphragm large enough to admit the fist; the viscera had slid through this opening: the stomach down to the pyloric region, the spleen and the greater omentum. There was no history of trauma in the case.

Hygiea, Stockholm

100 *Tuberculosis Mortality at Stockholm. E. Lindhagen.—p. 497.
101 *The Exudative Diathesis. A. Lichtenstein.—p. 544.

June 16, 1918, **80**, No. 11

102 The New Era in the Study of Syphilis. G. Ahman.—p. 671.

100. **Tuberculosis Mortality at Stockholm.**—Lindhagen's analysis of the tuberculosis mortality at Stockholm during the last few decades shows that it is considerably higher than that of Christiania and Copenhagen. The decline in the mortality since 1881 has been only 39.3 per cent. while in Christiania it has been 43.7 per cent. and in Copenhagen 56.4. His tables show a remarkable decline in the general mortality at all ages under 60, the difference amounting to 66 per cent. for children under 1 year old and 77 and 70 per cent. for children of 1 to 5 and 5 to 10. The tuberculosis mortality in women was only two-thirds that of men. The mortality between the ages of 15 and 40, both sexes, has declined very little in the last twenty years or has even increased a little. Between the ages of 15 and 20 the tuberculosis death rate in women has increased by 18 per cent. while that of men has been reduced by 12 per cent.

101. **The Exudative Diathesis.**—Lichtenstein presents an able exposition of what is meant by the exudative diathesis and the measures required to combat it, with analysis of about seventy-three different European publications on the subject. He emphasizes that treatment must seek to prevent and cure the various symptoms, as the diathesis itself cannot be transformed by our efforts. Surgical and medical measures are called for with the exudative diathesis, as well as dietetic measures. Atropin has never proved satisfactory in his hands in treatment of the eczema, but it has been strikingly effectual in treatment of the tendency to asthma in some cases, while others did not seem to derive any benefit from it. Children with the exudative diathesis should be guarded against infections of all kinds with special care. The conception of the exudative diathesis represents progress in the insight it has afforded as to the influence of diet on the course of a diathesis. But we have taken only the first steps in the field thus opened up. All the means for research in biology, chemistry and pathology should be called to aid in seeking the pathogenesis of the diatheses, the therapeutics, the diagnosis of latent diatheses, and the nucleus for the diatheses in questions of heredity.

103 *Diabetes. V. Scheel.—p. 1039.
104 *Test for Albumin. Lilliendahl-Petersen.—p. 1054.
105 *Vaginal Sarcomas. E. Himmelstrup.—p. 1056.

103. **Pathology of Diabetes.**—Scheel remarks that as a general thing theories in regard to diabetes follow on practice, instead of practice being based on theoretical reasoning. The connection between high sugar content of the blood and diabetes is still a question; he reports a case in which diabetes developed in a man of 59, apparently from a trauma. The sugar content of the blood was 0.30 per cent. (0.08 to 0.10 is the normal range), but the urine showed less than 0.5 per cent. sugar and none at all when the blood sugar had been reduced to 0.17 per cent. on antidiabetic diet, not even when the carbohydrates were given freely up to 80 gm. a day. There were no evidences of acetonuria at any time. At first there was some disturbance in vision, but this subsided with the hyperglycemia. There was no albuminuria and the blood pressure was only slightly above normal. Experience has shown that the blood sugar and urine sugar may behave in diabetes with chronic interstitial nephritis just the same as in others free from nephritis. The permeability of the kidneys for sugar does not seem to be modified by kidney disease. The latest research, on the other hand, has confirmed the importance of disease of the pancreas as a factor in diabetes, and that hormones from the chromaffine system are likewise involved.

In discussing the formation of sugar from fat, he relates the case of a diabetic man of 35 who was in the hospital for a year and a half, and the metabolic findings were recorded each day. In one thirty-day period the intake of carbohydrates was 3,525 gm. and the output 5,925 gm.; the intake of albumin 262 gm.; the output of nitrogenous substances, 297 gm. No assumption to explain this seems plausible except that the excess of sugar was formed from fat.

104. **Quantitative Determination of Albumin.**—Petersen remarks that the reagents for the usual tests for albumin are difficult to obtain at present. He proposes what he asserts is an excellent substitute for Claudius' reagent, while it is inexpensive and available. Comparative tests with the Esbach and Claudius methods have demonstrated its reliability. The formula for the reagent is phosphomolybdic acid, 2 gm.; concentrated sulphuric acid, 6 gm.; kaolin, 6 gm., and distilled water to 400 gm. It is used like the Esbach reagent, but takes only six hours. He prefers for the test an ordinary centrifuge glass, graduated as for the Claudius test.

105. **Vaginal Sarcoma in Little Girl.**—Himmelstrup has found records of thirty-three cases of primary vaginal racemose sarcoma, like the case he describes in a girl of 4. The majority were in children under 3. Operative measures gave only brief respite, all the patients dying in a year or two after the first symptoms.

INFANTILISM AND OTHER HYPOPLASTIC CONDITIONS OF THE UTERUS*

EMIL NOVAK, M.D.

BALTIMORE

Infantilism of the female genital organs may be only a local manifestation of general infantilism (infantilismus universalis). More frequently, however, it is observed in women who, aside from the genital organs, present no recognizable defects in development, and who, for that matter, may be unusually well developed. It is this local form of infantilism (infantilismus partialis or genitalis) with which we are concerned in this paper. Its very great frequency can be attested by every gynecologist, although I know of no figures bearing on this point. The clinical importance of the condition rests chiefly on two considerations: (1) the frequency with which it is associated with aberrations of the menstrual function, and (2) the fact that it often seems to constitute the anatomic basis for sterility.

Strictly speaking, the term "infantile uterus" should indicate that the organ resembles that normally found in the infant. The development of the uterus may, however, be arrested even as early as in the fetal stage, while on the other hand, the inhibition of development may not come until the prepuberal epoch. No practical advantage is to be derived from making very fine distinctions along this line, since the difference between the uterus of the fetus, the infant, and the child up to the prepuberal age is not nearly so great as one might be inclined to expect. Very frequently, the differentiation between the various types is not possible clinically. For this reason, it is perhaps not worth while to criticize the common custom of designating as an "infantile uterus" any uterus that presents noteworthy defects of development.

The observations herein noted are based on the study of twenty-six uteri that were removed at necropsy from subjects varying in age from the twelfth week of fetal life to the fourteenth year of postnatal life. For supplying me with a portion of this material, I am indebted to the members of the Pathological Staff of the Johns Hopkins Hospital. The uteri in the series were derived from nine fetuses, and seventeen infants and children of various ages. Among the fetuses, the age of one was placed at 12 weeks, of three at 5 months, of two at 6 months, and of three at between 8 and 9 months. Of the babies and children, two were stillborn at term; one was 5 days old; one, 10 days; one, 2½ months; two, 4 months; one, 6 months; one, 8 months; one, 9 months; one, 13 months; one, 15 months; one, 2 years; one, 2½ years; one, 4 years; one, 9 years, and one, 14 years. In studying this material, special attention has been given to the position of the uterus, its relation to the other pelvic organs, its size, its form, the relation existing between its different portions, and the presence or absence of flexions. For microscopic study, sagittal sections of the uterocervical canal have been found most satisfactory. The tubes and ovaries have been studied in most of these cases, but with the results of this study we are not concerned in this paper.

THE UTERUS IN FETAL LIFE

The characteristics of the uterus during the early stages of fetal life are well shown in Figure 1, which represents a sagittal section of the pelvis of an embryo of 76 mm. in length. This corresponds to an age of about 12 weeks. This specimen I was enabled to study through the kindness of Dr. George L. Streeter, acting director of the Carnegie Institute of Embryology. It can be seen that the uterine canal scarcely permits of differentiation into cervix and corpus. It is merely a straight tube of uniform caliber, although the upper sixth or so obviously represents the future fundus. The high position of the uterus at this age can be appreciated by observing that it is almost entirely above the level of the symphysis, that is, that it is essentially an abdominal organ, like the bladder at this stage. It is uncommon to see either sharp anteflexion or retroflexion at this period, although a moderate antecurvation of the uterus (uterus antecurvatum) is very frequent — indeed, it may be said to be the rule in the later stages of fetal life.

Throughout the whole fetal epoch a preponderance of the cervix over the corpus uteri is noteworthy. The well known characteristics of the epithelium in the different portions of the adult canal do not become noticeable until the fetal development is far advanced. As in the adult, the cervix is then lined by tall, slender "picket" epithelium, while the corpus is covered by cells of a shorter and broader columnar type. The time of the appearance of gland elements is quite variable. In some uteri they are as well developed, especially in the cervix, in the last period of fetal life as they are in others during the fifth or six year of extrauterine development. Toward the very end of the fetal phase, the uterus exhibits a rather striking acceleration of growth, affecting the fundus as well as the cervix. After the birth of the child there is a rather pronounced shrinkage or involution of the fetal uterus, as will be discussed later.

---

* From the Gynecological Department of Johns Hopkins University.

* Read before the Section on Obstetrics, Gynecology and Abdominal Surgery at the Sixty-Ninth Annual Session of the American Medical Association, Chicago, June, 1918.

* Because of lack of space, this article is abbreviated in The Journal. The complete article appears in the Transactions of the Section and in the author's reprints. A copy of the latter will be sent by the author on receipt of a stamped addressed envelop.

THE UTERUS OF INFANCY AND CHILDHOOD

These two epochs are placed together because of the fact that, to all intents and purposes, the uterus is a stationary organ throughout both periods. It would be difficult to distinguish, either from size or from shape, between the uterus of the child of 1 year and the child of 8 or 9 years. As compared with the fetal uterus, there is perhaps a lesser degree of disproportion between the cervix and the corpus, the latter having become a little longer and somewhat more clearly differentiated (Fig. 2). The occurrence of sharp anteflexion, and, to a less extent, of retroflexion, is far more common during this stage than during fetal life. The explanation of this fact will be discussed under another heading.

THE UTERUS AT PUBERTY

With the awakening of the ovaries at puberty comes a very remarkable stimulation of uterine growth. Within a short period, the uterus may almost double its size. A comparison of two of my specimens, one representing the uterus of a 9 year old child, and the other that of a girl of 14, gives a vivid impression of the change in uterine size and form that puberty brings with it. The 9 year old girl's uterus is 35 mm. long, while the uterus of the 14 year old girl, who had just commenced to menstruate, measures 57 mm. in length. There is relatively little difference in the length of the two cervices, one measuring 22 mm. and the other 27 mm. The body of the 14 year old uterus, however, is more than twice the length of that of the 9 year old organ, measuring 30 mm., while the latter is only 13 mm. long. In addition, there is a very striking difference in the width and in the thickness of the walls of the two uteri. The characteristics of the 14 year old uterus are those of the adult organ—the well developed convex fundus which is at least equal to the cervix in length, the thick musculature, and the regular monthly cycle of histologic changes in the endometrium (Fig. 3).

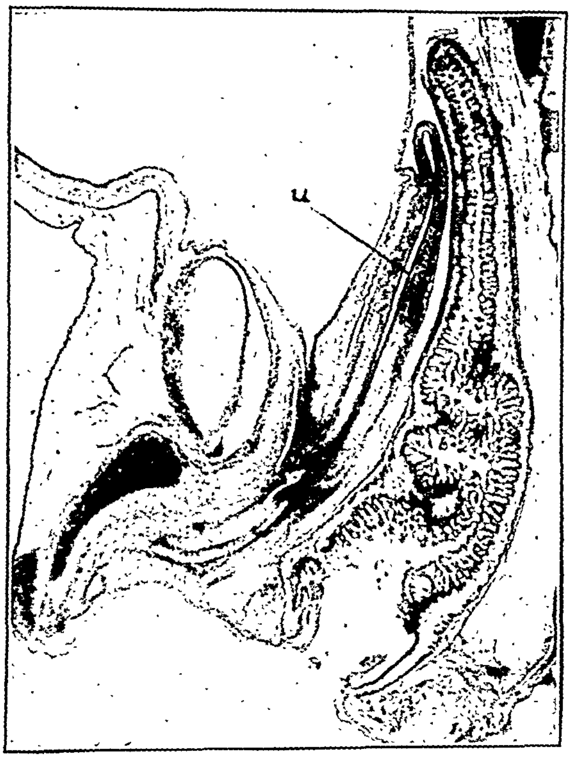

Fig. 1.—Sagittal section of pelvis of 12 weeks old fetus, showing characteristic fetal uterus (*u*), made up almost entirely of cervix.

THE QUESTION OF THE ISTHMUS UTERI

The usual division of the uterus into the corpus uteri and the cervix uteri has much to commend it, especially from the point of view of simplicity. On the other hand, there are some advantages in the less popular plan suggested by Aschoff in 1906,[5] of considering the uterus to be made up of three segments, namely, the corpus, the cervix and the isthmus uteri. Certainly the isthmus possesses distinctive histologic characteristics which entitle it to separate consideration, and which, as I shall show, are of no little significance in the explanation of certain physiologic and pathologic occurrences.

From an obstetric standpoint, this segment of the uterine canal is of great importance by reason of the fact that the lower uterine segment of the parturient uterus is derived from it. A bitter controversy, stretching over a number of years, and still unsettled, has been waged among German obstetricians as to whether the lower uterine segment is to be looked on as derived from the cervix alone or from both the cervix and the corpus uteri. With this discussion we shall not here concern ourselves, except to say that the weight of evidence points to the correctness of the latter view. The problem is made much simpler if we apply to it the three segment conception of the uterus, that is, if we distinguish, in addition to the cervix and corpus, a third connecting segment, or isthmus. The os internum anatomicum, which is the upper limit of the isthmus, corresponds to the contraction ring of Braune (Bandl), while the lower limit of the lower uterine segment is the os internum histologicum. In other words, according to this division, the isthmus of the nonpregnant uterus exactly corresponds to the lower uterine segment of the parturient woman.

The gynecologic importance of the isthmus rests principally on the fact that congenital flexions of the uterus probably always take place at the isthmus. Furthermore, although this cannot be stated with the same support of histologic study, it is probable that the acquired flexions of later life also occur at the same segment. Its designation by Aschoff as the *Scharnier* or "hinge" of the uterus would thus seem to be justified. It is common to observe flexion of the uterus, usually in the form of anteflexion, in very early life. In every such anteflexed uterus that I have been able to study microscopically, the angle of flexion has been in the middle of the isthmus and not at the internal os, as has so generally been believed. Opportunities for study of congenital anteflexion of the uterus in adult women are scarce, as such uteri are rarely removed at operation, and necropsy material of this sort is hard to obtain. Indeed, I know of but one observation along this line, that of Hegar.[6] The uterus was removed by vaginal hysterectomy from a girl of 24, on account of severe dysmenorrhea that had resisted all other forms of treatment. The uterus was sharply anteflexed—as Hegar terms it, "hyperanteflexio uteri congenita." Examination showed three well marked segments with the histologic characteristics already described. The angle of flexion was within the limits of the well marked isthmus. Congenital retroflexions are far less frequent than anteflexions. No example has been seen in my series. There can be no doubt, however, that, as with anteflexions, the point of angulation is in the isthmus. The same may be said of lateroflexion, slight degrees of which are very common in fetal and infantile uteri.

---

[5] Aschoff: Ztschr. f. Geburtsh. u. Gynäk., 1906, **58**, 328.

[6] Hegar: Beitr. z. Geburtsh. u. Gynäk., 1909, **14**, 141.

Flexions of the uterus are far more commonly observed in the uterus of the infant or young child than during fetal life. I believe that this is due to the fact that in the fetal organ the isthmus is practically undeveloped, while, on the other hand, in the infantile uterus, it forms a large and important segment. It is easy to see how abnormal length and flexibility of the uterine isthmus may result in the production of flexion of one form or another. Once the uterus becomes angulated, the flexion must be looked on as permanent. After the age of puberty the isthmus becomes small and more or less vestigial, so that it is probable that acquired anteflexion rarely occurs during this epoch.

The point that I should like to reemphasize is that it would be of value to the gynecologist to think of the uterus as a composite organ, in the sense that it is made up of three separate segments. At various periods of life one or the other of these segments predominates in size and perhaps in function. Each segment apparently has its own function, and each seems to be under the control of a different endocrine influence. Such a conception as this would seem to be more in accord with fact and more conducive to fruitful observation than the custom of looking on the uterus as merely an organ entity in itself, going through various physiologic and pathologic changes *en masse,* as it were.

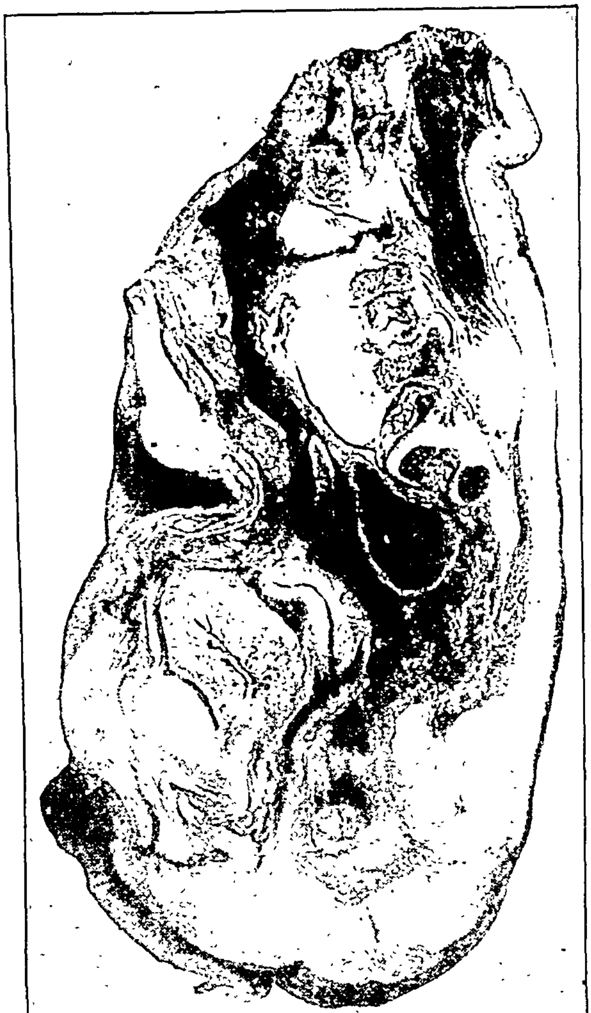

Fig. 2.—Sagittal section of pelvis of infant of 9 months. The division of the uterus into cervix and corpus is clear, the former still greatly predominating. Note also the anteflexion of the uterus.

TYPES OF UTERINE HYPOPLASIA

Throughout the consideration of this subject it is important to remember that hypoplasia may manifest itself in either one of two principal ways — an arrest of growth or an arrest of differentiation. Perhaps the best analogy to bear in mind in this connection is furnished by the striking work of Gudernatsch[8] on the effects of thyroid and thymus extracts on tadpoles. On the administration of thymus, the tadpoles grew to very large size, but still remained tadpoles. Feeding with thyroid, however, produced an altogether different result—the tadpoles developed rapidly into frogs. Under normal conditions, the growth and differentiation of the uterus proceed more or less hand in hand. Under certain conditions, however, it would appear that one may lag far behind the other, so that we may see a uterus equal in size to the normal adult organ, and yet having the form and segmental proportions of the infantile uterus. On the other hand, in those cases in which growth seems to have been retarded, while differentiation has proceeded normally, a very much undersized uterus may have the form of the normal mature organ.

The Uterus Foetalis. — The development of the uterus may be arrested in the fetal, or embryonic, stage, in which case it possesses the characteristics already described for the fetal uterus. This so-called uterus foetalis (uterus embryonalis, uterus rudimentarius) is made up almost entirely of cervix, the fundus being extremely rudimentary. As a matter of fact, it may be almost impossible to distinguish any differentiation into two segments. The uterocervical canal is either straight or slightly antecurved. Anteflexion is uncommon at this stage. The characteristics of this type of uterine hypoplasia are well shown in Figure 4.

The Uterus Infantilis. — This term, strictly speaking, should be restricted to the uterus whose development has been arrested during the period of infancy or childhood, for as has been shown, the infant uterus does not differ materially in form from that of the child up to the age of puberty. The cervix still definitely predominates over the corpus, but the two are now clearly differentiated. The fundus is much better developed than in the infantile uterus, and its walls are also somewhat thicker. It still lacks, however, the broad convexity that is characteristic of the mature uterus. Anteflexion is a common but by no means invariable finding, the angle of flexion being always within the limits of the isthmus (Fig. 5). The anteflexion is usually of the cervicocorporeal type, the small conical cervix pointing downward and forward in the axis of the vagina, while the fundus is bent forward on the cervix, often at a very acute angle. Hegar divides infantile uteri into two principal groups: 1. Those in which the uterus possesses the infantile characteristics above enumerated, especially as concerns the predominance of the cervix, but in which the organ is of normal size. This type he calls "the uterus infantilis nonhypoplasticus." 2. Those in which the size and shape of the uterus are infantile, the so-called "uterus infantilis hypoplasticus."

The Uterus Subpubescens. — In some respects the most interesting forms of uterine hypoplasia are those of mild degree—those in which the inhibition of development does not assert itself until the prepuberal period. The difference between the uterus of this type and the normal pubescent organ is often slight, so that the designation of this group as "subpubescent" would seem fitting. When the ovarian influence, so important at puberty, is tardy in its appearance, the fundus remains undeveloped; that is, there is a persistence of the infantile type already described. In other cases, again, the anatomic defect of the fundus may be very slight, so slight as to be scarcely appreciable clinically. All possible grades of hypoplasia may be distinguished between these two extremes. As in the infantile group, anteflexions are very common and are usually of the cervicocorporeal variety (Fig. 6).

---

[8] Gudernatsch: Am. Jour. Anat., 1914, **15**, 431.

CLINICAL CHARACTERISTICS OF UTERINE HYPOPLASIA

Both of the two great functions of the uterus—menstruation and reproduction—are profoundly influenced in the various forms of uterine hypoplasia. As regards the effect on menstruation, we may distinguish two groups of cases. In one type, which may be spoken of as the "amenorrheic," the predominant symptom is amenorrhea or scanty menstruation, with little or no dysmenorrhea. In the second group, on the other hand, the conspicuous symptom is dysmenorrhea, the amount of flow being most frequently scanty, but sometimes being normal or even excessive. This second type may be designated as the "dysmenorrheic." No sharp dividing line can, of course, be drawn between the two groups, the symptoms often overlapping to a certain degree.

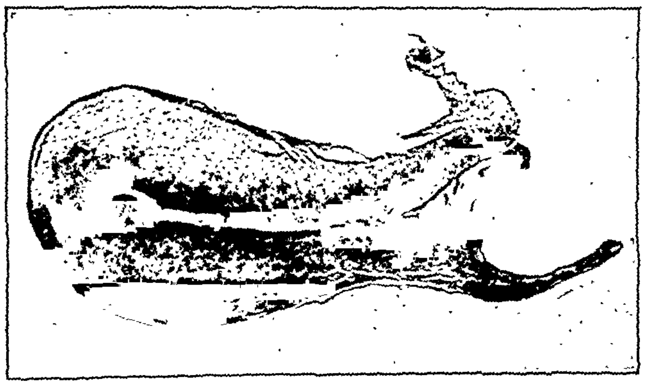

Fig. 3.—The uterus of a girl of 14, showing the great development of the corpus uteri at puberty. Note the convexity and the thick walls of the fundus.

The amenorrheic syndrome is constant in the extreme forms of uterine hypoplasia, such as uterus rudimentarius. Furthermore, it is often observed with the infantile uterus. On the other hand, menstruation may be normal, or perhaps even excessive, in those cases in which the fundus is only slightly subnormal. Secondarily, of course, amenorrhea may be observed even in large, well developed, and perhaps multiparous uteri, as in the well known Fröhlich's syndrome, which is due to hypopituitarism. Were it possible to exclude in any way the influence of the various extragenital endocrine bodies, which, of course, is not the case, the development of the uterine body could be looked on as, in a general way, an indication of ovarian activity. Certainly, as has already been emphasized, it is the fundus and not the cervix which is functionally linked with the ovaries.

Dysmenorrhea is observed far more frequently in the milder degrees of hypoplasia than in very rudimentary uteri. The reverse is the rule with amenorrhea, which is always seen with the rudimentary type of uterus, but is often lacking in the slightly subnormal. Always remembering, of course, that we are dealing with only the primary types of amenorrhea and dysmenorrhea, the conclusion seems warranted that, as a symptom, amenorrhea is indicative of a greater degree of hypoplasia than is dysmenorrhea.

The clinical manifestations of congenital hypoplasia may be conveniently studied under two headings: (1) symptoms associated with the menstrual function, and (2) those associated with the reproductive capacity.

The Menstrual Symptoms.—Retarded Puberty: In many cases of uterine hypoplasia, as observed in the adult woman, inquiry reveals that menstruation was inaugurated at a period much later than usual. Instead of appearing at the age of 13 or 14 years, the function in many of these cases is established perhaps as late as 17 or even 19. If the age of puberty is very much retarded, and especially if retardation of the menstrual function is associated with absence of such secondary sex characteristics as development of the breast or the appearance of hair over the mons and in the axillae, congenital hypoplasia is usually only a local manifestation of a general underdevelopment, the result of a more or less profound endocrine disturbance.

Amenorrhea or Scanty Menstruation: Menstruation is much more likely to be deficient than excessive in cases of uterine hypoplasia. This, as has already been emphasized, is especially true of the more advanced grades. I have reviewed the histories of sixty cases from this point of view. The cases in this series included uteri that were described by such terms as "infantile," "small and anteflexed," etc. It was probably made up chiefly of uteri of the infantile and subpubescent groups. A subdivision was made into those in which the menstrual flow was scanty and those in which it was not deficient, that is, those in whom, as far as could be judged from the patient's own statement, the amount of flow was either moderate or profuse. In thirty-eight cases menstruation was scanty, in twenty-two it was either moderate or excessive. The findings in this small series of cases, in spite of the crudity of the method of study, are nevertheless in accordance with general experience. In the marked cases of uterine hypoplasia, in which amenorrhea is practically always seen, there is usually associated with it a greater or less degree of constitutional change, most commonly adiposity. This syndrome—sexual hypoplasia and obesity—is the same as that which is so characteristic of the acquired condition, which is now so clearly recognized as "adiposogenital dystrophy," or Fröhlich's syndrome. Like the latter, it is probably due to a hypopituitarism, one condition being congenital and the other being acquired. In the less severe forms of hypoplasia, menstruation may not be altogether absent, its rhythm and amount being in a general way indicative of the degree of hypoplasia of the uterus. As to the cause of the amenorrhea in these cases, three factors must be considered:

1. Endocrinopathies of one form or another, involving especially the ovary or the pituitary, may furnish the responsible factor.

2. The small area of the endometrial surface may explain the menstrual deficiency. Since the menstrual blood has its source in the endometrium,

it is easy to understand how a lessening of the latter may, other things being equal, lessen the amount of menstrual blood lost, just as the increase of the endometrial surface in cases of adenomyoma of the uterus may cause excessive menstrual bleeding.

3. It is possible that the anatomic defect in the uterus may be associated with a defect in the physiologic function of the endometrium. As I have elsewhere emphasized, the endometrial hyperemia evoked by the ovarian hormone is not in itself sufficient to explain the bleeding of menstruation. Such an idea would be foreign to our conception of the nature of hyperemia, which is never associated with any such wholesale exodus of blood elements from the vessels to the surrounding tissues as is seen in the course of menstruation. It seems essential to assume that some local physiologic factor in the endometrium must be responsible for the increased permeability of the blood vessels, which allows of this menstrual migration of blood corpuscles from the vessels. While little scientific evidence can as yet be brought forth to support the idea, it is possible that the amenorrhea in cases of uterine hypoplasia is due to a deficiency of this local physiologic factor.

Dysmenorrhea: The existence of even extreme grades of hypoplasia of the uterus, with the amenorrheic clinical syndrome already described, is not incompatible with perfect health and well-being. On the other hand, the milder forms of hypoplasia are often associated with spasmodic dysmenorrhea of so severe a grade as to wreck the physical and nervous constitution of the patient. As a rule, this type of menstrual pain makes its appearance a day or two before the actual onset of the flow, continuing usually until the latter is well established. It is commonly described as cramplike or colicky, differing from the congestive type of dysmenorrhea in that the latter is usually dull, aching and constant. Examination of patients suffering with spasmodic dysmenorrhea often reveals that the uterus is not only hypoplastic but also anteflexed; hence, it is not surprising that the anteflexion is usually held responsible for the menstrual pain. As a matter of fact, it was this frequent association of anteflexion and dysmenorrhea that led Mackintosh, as far back as 1836, to urge the importance of mechanical obstruction in the uterine canal as the cause of dysmenorrhea: "Nulla dysmenorrhea nisi obstructiva," as Marion Sims put it.

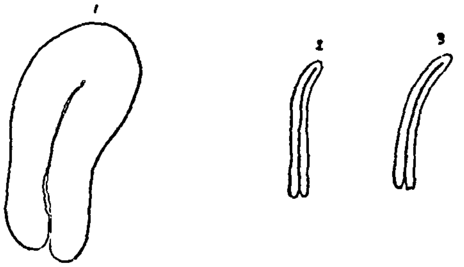

Fig. 4.—Illustrating the fetal type of uterine hypoplasia, (2) and (3), as compared with the normally developed uterus (1).

Evidence is accumulating, however, to show that the uterine flexion and the dysmenorrhea are not to be looked on in the relation of cause and effect. As many cases of primary dysmenorrhea are observed without anteflexion as with anteflexion. Furthermore, it is common to find even sharp anteflexion without dysmenorrhea. Herman[9] states that fully one half of all nulliparous women have anteflexed uteri, so that it is not at all surprising that dysmenorrhea and anteflexion often coincide. Finally, it has been shown that in dysmenorrheic women in whom there is also an anteflexion of the uterus, a probe can easily be passed into the uterine canal during the height of the menstrual pain, indicating the absence of any actual obstruction. The proof seems quite convincing that, while anteflexion and dysmenorrhea often coexist, there is no direct relationship between them.

As to what is actually the cause of the spasmodic dysmenorrhea so frequently observed in young women with defective uterine development, we are unfortunately not in a position to speak with any degree of certainty. I have elsewhere recorded studies indicating that the endometrium of hypoplastic uteri exhibits the usual menstrual cycle of histologic change seen in normally developed uteri.[10] In the paper referred to I suggested that the hypoplasia involves the uterine musculature more than it does the mucosa, and that the dysmenorrhea may be due to the inability of the endometrium at the time of menstruation to be accommodated within the undersized uterine cavity. The uterine muscle is thereby excited to cramplike contractions in an effort, as it were, to expel its own endometrium. This conception would seem to be borne out by the fact that the menstrual pain in these cases is usually relieved as soon as the menstrual flow is well established, that is, as soon as the swelling of the endometrium diminishes.

Sterility.—As to the cause of the sterility that is observed so frequently in connection with hypoplasia of the uterus, it is difficult to believe that the small size of the uterus or any histologic peculiarity of its mucosa has any important bearing on this matter. If an impregnated ovum can implant itself on the wall of the fallopian tube, which is certainly not adapted for gestation purposes, there would seem to be no anatomic reason why it should not take root in even a very rudimentary uterus; and yet this never happens. In an indirect way, at least, it can be shown that the ovaries may function normally in cases of uterine infantilism, so far as the menstrual process is concerned.[10] It would seem probable, therefore, that the bar to conception must lie within the uterus and probably within the mucosa. Since the latter is histologically normal, we must apparently explain the sterility as a manifestation of pathologic physiology, rather than pathologic anatomy.

There is now a fairly general acceptance of Fraenkel's view that the corpus luteum, in addition to its menstrual function, is also of importance in maintaining the fixation of the ovum in the early part of pregnancy. It is possible, therefore, that in these cases of genital hypoplasia this local factor in the endometrium is lacking, preventing the implantation of the ovum. Adler's work[12] indicates that the presence of this important local element, whether hormone or enzyme, is dependent on corpus luteum activity, so that, in the final analysis, sterility of this type can perhaps be explained as due to disturbances of the endocrine system.

TREATMENT

What little I shall have to say about treatment will be limited largely to comments on the methods in vogue at present. The treatment of hypoplasia of the uterus is unsatisfactory, because it cannot in the present state of our knowledge be directed to the underlying cause of the condition. As has been brought out, the defective development of the uterus in these cases is almost surely due to some form of endocrine disorder. Which of the ductless glands are concerned, what the nature of the disorder is, and how best to correct it—all these are problems still unsolved.

[10] Novak, Emil: Surg., Gynec. and Obst., 1915, **21**, 336.

[12] Adler: Arch. f. Gynäk., 1912, **95**, 349.

Organotherapy has, of course, already been resorted to by many on the slim basis of the few facts that seem fairly well established. Ovarian extracts of one orm or another, either of the whole organ or of the corpus luteum alone, have been given either by mouth or hypodermically. Important as the corpus luteum is in menstruation, and valuable as its administration may be in certain menstrual disorders, I know of no evidence indicating that this structure plays any part whatsoever in the development of the uterus. As a matter of fact, developmental defects of this organ commonly arise long before puberty, that is, long before corpora lutea are found in the ovary. It seems justifiable to conclude that if organ extracts are to be given in cases of uterine hypoplasia, the ones to be chosen are extract of the whole ovary or extracts of other ductless glands that probably play an important part in the early growth of the genital canal. Pituitary extract suggests itself in this connection, as well as the still unsatisfactory extracts of the pineal and thymus bodies. Suffice it to say that this method of treatment has been carried out by various workers, with very little success. Failure does not, however, necessarily invalidate the correctness of the theories on which this treatment is based. It is far more likely to be due to the imperfection of our knowledge as to the active principles of the various ductless glands and of the technic of preparing extracts for clinical use. Much might be said in the discussing of this one point, but there is little doubt that the persistent groping of clinicians and laboratory investigators will sooner or later lead us into the light. The type of hypoplasia may be of some importance in suggesting the plan of treatment. Theoretically, ovarian extracts would seem to be indicated especially in the subpubescent group, while pituitary extracts suggest themselves in the treatment of the fetal and infantile type of uteri.

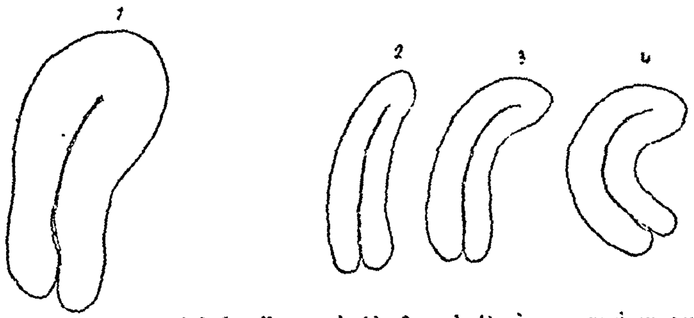

Fig. 5.—Types of infantile uteri (2, 3 and 4), in comparison with the normal uterus (1). In all the cervix predominates over the corpus. In 3 is shown a moderate corporeal anteflexion, while 4 illustrates the more characteristic cervicocorporeal anteflexion. In some cases the cervix is normal, in others long and conical, with pinhole os. Uteri of infantile form may be of practically normal size.

Aside from this as yet undeveloped plan of treatment by organ extracts, the treatment of uterine hypoplasia presents a more or less composite problem, being really directed to the treatment of a whole group of symptoms and allied disorders, especially amenorrhea, dysmenorrhea and sterility. One or more of these clinical manifestations usually brings the patient to the physician for treatment, as without them she would be ignorant of the existence of the hypoplasia.

Unfortunately, amenorrhea is often treated by practitioners of medicine as if it were a disease in itself, rather than a mere symptom. Unlike excessive menstrual bleeding, the cause of amenorrhea is far more frequently constitutional than local. In the amenorrhea of uterine hypoplasia, however, we have to deal with a local anatomic defect in the genital system, although this is quite possibly secondary to a constitutional endocrine disturbance. At any rate, little benefit can be expected from hematinics and emmenagogues, so often prescribed in these cases. The administration of the latter is especially to be decried. How a drug supposedly causing merely a pelvic hyperemia can be expected to establish such a regularly recurring physiologic process as menstruation, I have never been able to understand.

As for the treatment of the dysmenorrhea so frequently associated with hypoplasia of the uterus, this also must be looked on as leaving much to be desired. During the actual attack, treatment is, of course, directed to the relief of the menstrual pain. The two drugs most effective for this purpose are the two that for obvious reasons are especially to be avoided, morphin and alcohol. Taken all in all, the drug that has in my experience given the best results in most cases—other than the two I have just mentioned—is atropin. This method of treatment, which I have described elsewhere,[13] is based on very rational principles, and its results, while not constant, are better than those yielded by any other drug treatment of which I know.

Not infrequently, the aid of surgery is invoked in the effort to relieve the intense suffering of primary dysmenorrhea. The operation most commonly done is that of dilatation of the cervix. Formerly, this was, as a rule, accompanied by curettage, but now, happily, it is seldom that we scrape away the perfectly normal endometrium which is practically always found in these cases. There is neither reason nor advantage in doing so. Holden's study[14] of the results of dilatation of the cervix in ninety-five cases of primary dysmenorrhea treated in the Gynecological Clinic of Johns Hopkins is far from encouraging. Forty per cent. of the patients were relieved for as much as one year, 7 per cent. of these suffering a later recurrence; 30 per cent. exhibited slight or temporary improvement, while the remaining 30 per cent. were in no way benefited by the operation. These figures, I believe, will about represent the experience of most gynecologists.

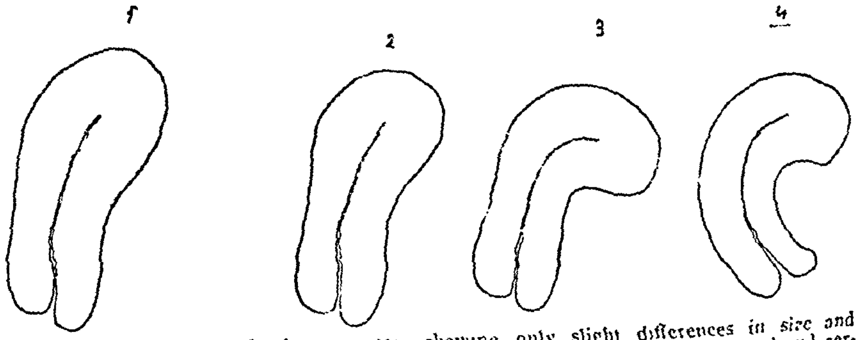

Fig. 6.—Types of subpubescent uteri, showing only slight differences in size and form from normal uterus (1) In 3 and 4 are shown, respectively, corporeal and cervicocorporeal anteflexion. Drawings in Figures 4, 5 and 6 by Miss Ethel Norris.

The employment of the stem pessary, so enthusiastically advocated by Carstens and others, is based on the idea that the pessary, by causing expulsive efforts on the part of the uterine muscle, exercises the latter and causes an increase in the development of the uterus. This plan of treatment is not without danger, as I myself have seen several cases of troublesome endocervicitis following the use of the stem pessary. To judge from the reports in the literature, however, the results are better than those following simple dilatation. As for the various plastic operations on the cervix that have at different times been advised for the relief of dysmenorrhea, such as those of Sims, Dudley, Pozzi, or that recently described by Frank, I can see absolutely no excuse for their performance. All of them are based on the erroneous impression that the dysmenorrhea is due to cervical stenosis; and all of them should, therefore, be abandoned.

[14] Holden: Am. Med., 1905, **10**, 776.

Much of what has been said by way of criticism of the present-day treatment of dysmenorrhea applies also as regards the sterility so frequently observed in the same group of patients. Dilatation with or without the subsequent use of the stem pessary, as well as plastic operations of one form or another, have been resorted to in an effort to relieve the sterility, with results even less gratifying than in the case of the dysmenorrhea. The reason for the failure of this method of attacking the problem lies in the fact that the sterility, as has already been discussed, is most likely due to a physiologic defect in the endometrium, that is, the absence of some factor essential to the implantation of the ovum. Here again we hark back to disorders of the internal secretory system as the ultimate cause. This, after all, is the conviction borne in on any one who studies this general problem, whether or not he be a ductless gland enthusiast or "faddist"—the conviction that the day will come when these very numerous cases of primary amenorrhea, primary dysmenorrhea and sterility, which are associated with uterine hypoplasia, will be successfully treated by correcting the endocrinopathy responsible for the uterine defect.

Utility of Birth Statistics.—The enforcement of legislation for the registration of births and the creation of a sentiment among all classes for the recording of proper vital statistics would, if undertaken at the present time, place us in the position of being able during the approaching census year to measure accurately the mortality among infants throughout the country. Not only should our efforts be confined to a complete registration of births but also to the necessity of more accurate statements of the causes of death on certificates of infants under 1 year of age. Certificates bearing as a cause of death such indefinite statements as marasmus, inanition, asthenia, convulsions and prematurity should, if not tabued, at least be queried as to underlying causes. With a complete registration of births many problems now occupying the public mind can be more intelligently discussed, such as illegitimacy, comparative fecundity of various race-stocks, the effects of hazardous occupations of parents on their generative faculties, and the determination of the ages of greatest fecundity.—W. H. Guilfoy, M.D., Tr. Am. Assn. for Study and Prev. of Infant Mortality.

VISCEROPTOSIS

A NEW OPERATION FOR ITS RELIEF *

J. RIDDLE GOFFE, M.D.
President, International Congress of Obstetrics and Gynecology; Professor and Attending Gynecologist, New York Polyclinic Medical School and Hospital; Consulting Surgeon, Woman's Hospital
NEW YORK

The vicious consequences of visceroptosis, both immediate and remote, are so manifest and so generally accepted by the profession that they need no amplification. The etiology is referred to congenital influences, the lack of proper early training and development, and to careless, indolent habits of standing, sitting, walking and general carriage of the body in all its attitudes. The condition per se may mechanically produce localized pain and distress and interfere deleteriously with nutrition by retention of food in the stomach and by constipation or stasis of the alvine current in its course through the intestine. The only satisfactory etiologic factor that explains the ulterior complex symptomatology is to be found, however, in the little mischief makers that generate ferments and toxins which, circulating in the blood, poison the nerve centers and the brain.

The neurologists go even further than this. They do not admit that it is necessary to await the appearance of ptosis to afford habitat for noxious bacilli, microbes or parasites — even Glénard referred to a period preceding ptosis and claimed that toxins of alcohol, fermenting food and the puerperium, of typhoid and malarial infections, traumas and even emotions of fright and chagrin, all or any one, acting through the autonomic or sympathetic nervous systems might be basic factors in causing structural changes in the viscera and their malposition in the abdominal cavity. This *a priori* theory of Glénard's has, since the establishment of the microbe theory of disease, been satisfactorily confirmed by physiologic experimentation. These structural changes cause stasis in the alvine current which, in turn, affords additional facilities for development of increased supplies of toxins; these, carried to the autonomous nerve centers, intensify in turn the deleterious changes in the viscera. Thus is established the vicious circle, or syndrome. In its complete form it includes the gastro-intestinal disturbances arising secondarily in the viscera; the pains in the abdomen due to organic changes in the viscera; kinking and other distortions in their walls; pressure on the nerve ends; the referred pains in other parts of the body; the crisis, accompanied by nausea, vomiting and collapse; and the neuropathic mental state of the patient, with its depressions, its querulousness, its maladjustment to environment and its great susceptibility to fatigue.

---

* Read before the Section on Obstetrics, Gynecology and Abdominal Surgery at the Sixty-Ninth Annual Session of the American Medical Association, Chicago, June, 1918.

* Because of lack of space, this article is abbreviated in The Journal by the omission of sixteen case reports and four roentgenograms. The complete article appears in the Transactions of the section and in the author's reprints. A copy of the latter will be supplied by the author on request.

The ptosis not only causes a retardation of the alvine current—a stasis—due to redundance, persistent dilatation, sharp angulation and kinks and adhesions that necessarily attend the displacement and the opposition of gravitation to the reversed direction of the current, but also subjects the vertebral ganglions and their connections to torsion, pressure and stretching, while absorption of the toxins overwhelms the sympathetic system, and perchance the brain centers as well.

TREATMENT

Four forms of treatment are to be considered and are indicated in this class of cases: (1) the skill of the internist, with all his resources to eliminate the toxins; (2) the physical culture expert with his gymnastic exercises, his postural treatment, his belts, his corsets and his high heeled shoes; (3) surgical treatment to restore normal position, relieve obstructive angulation, false adhesions, and pressure and drag on the sympathetic ganglions; and (4) neurologic treatment to relieve the depressive emotional disturbances. This does not necessarily imply four distinct specialists but, rather, one broad minded surgeon who embraces them all, and should with reasonable cooperation on the part of indicated specialists actually be able to handle the different phases of treatment in the majority of cases.

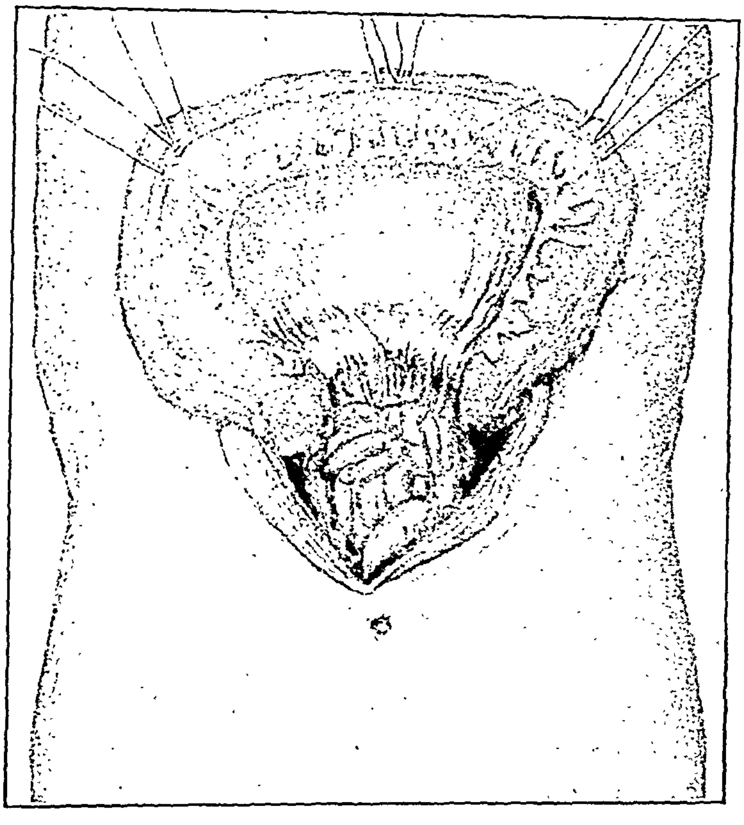

Fig. 2.—The sutures as applied to the colon.

The postural, gymnastic and corset treatment is a most excellent prophylactic in early life in patients exhibiting a constitutional hereditary predisposition, what Steller calls the habitus enteroptoticus of asthenia universalis congenita, that is, patients with forward protrusion of head and chin, long arms, thin neck, narrow elongated chest, sloping shoulders, lack of adipose, flat abdomen and pot belly. A strict regimen, such as described by Reynolds and Franklin Martin, persistently carried out and continued for years will correct much and prevent more; but the rub comes in carrying the patient along to the sticking point beyond which relapses may not occur. It is a tiresome, discouraging job for both patient and physician.

When the patient has reached the stage of actual ptosis of stomach and colon, in which angulations have become obstructive and adhesions have formed, nothing can avail but surgical interference. The extreme colectomy of Arbuthnot Lane is rarely indicated unless we accept the teachings of Reed that therein lies the final efficient corrective for epilepsy. But certainly nothing is more rational than the relief of obstructive angulations, adherent kinks and painful pressure by the permanent restoration to normal position of the overstretched, tired out, devitalized structures. Many methods have been devised to accomplish this end, some of which have stood the test of time and have apparently become standardized. It is not my purpose to go into an analytic discussion of them or indulge in comparisons. My mission is to present a method which I have evolved in dealing with cases of visceroptosis. It has been put to a sufficient test, I think, to make it worthy of consideration.

My first experience was gained in 1889:

Case 1.—A woman about 25 years of age, an expert stenographer and typewriter, a nervous dyspeptic and neurasthenic wreck, had a ptosed and dilated stomach. After treating her medicinally and washing out her stomach morning after morning before breakfast for weeks and months without much improvement, she announced to me one day that she was tired of treatment and ready for the operation I had discussed with her some weeks previously. Accordingly she went to the Polyclinic Hospital and was made ready for the operation. Through a free incision above the umbilicus, I plicated the anterior wall of the stomach, parallel to the long axis. Just above this line two sutures were passed perpendicular to it through the peritoneal and muscular wall of the stomach. Both ends of each suture were then carried up through the peritoneum and fascia of the abdominal wall, but not the skin, and made to appear, each on its own side, in the upper angle of the abdominal wound. After the closure of the peritoneum the two ends of each suture were tied, cut short and buried in the closure of the abdominal incision. I had heard Dr. Emmet tell many a time, during my service at the Woman's Hospital, of suspending the woman slaves of the South between trees in hammocks with their heels higher than their heads for the relief of prolapse of the uterus. It occurred to me that this posture would assist in taking the strain off the stomach sutures, and when the patient was put to bed, the foot of the bed was elevated by a chair placed under the foot, thus securing what is familiarly known as the Trendelenburg posture This was maintained for two weeks, when the bed was gradually lowered to normal at the end of three weeks, the patient leaving the hospital at the end of the month.

Perfect success attended the procedure. The patient gained flesh and nerve power, returned to her work in three months, and continued it successfully while under my occasional observation for several years.

AUTHOR'S METHOD

From this experience I gradually evolved the method I now employ. This description embraces the complete operation in which both stomach and colon are involved in extreme ptosis and adhesions. Of course, not all the steps described are indicated in every case.

A longitudinal or transverse incision is made below the umbilicus. Through this adhesions are severed, the organs set free, the appendix removed, the caput, if overdistended, plicated; the uterus, which is frequently found displaced, restored to normal position and supported there, and, if necessary, the appendages dealt with as indicated. The incision is closed.

A longitudinal incision is then made above the umbilicus through which the upper abdominal cavity is thoroughly explored with the hand, note being made of the condition of the liver, its ligaments, the gallbladder and ducts especially. Any pathologic conditions discovered are dealt with according to indications, new incisions being made or the original one enlarged if necessary.

The stomach is then delivered through the wound, and inspected and palpated for ulcers and pyloric irregularities. If dilated, the anterior wall is depressed with a sound along the middle line, and over this the stomach wall is plicated in a double row of linen sutures. In a line just above or below this, and midway between the extremities of the stomach, two or more linen sutures are threaded along in the stomach wall, including the peritoneal and muscular coats, each one being buried for from one-half to three-fourths inch. The stomach is returned to the abdominal cavity. The sutures still untied are left long and protruding from the wound, wrapped in sterile gauze. The transverse colon is now delivered through the wound, the omentum ligated along the border of the intestine and cut away. The hepatic flexure is picked up and two sustaining linen thread sutures are threaded along in its walls similar to those in the stomach, left long and protruding through the wound and protected by sterile gauze. Next the splenic flexure is exposed and treated similarly, and finally the transverse colon at its middle section. These sutures are all passed either just below the attachment of the mesocolon or in the broad band of the colon. The latter is firm and holds well, and is to be preferred when the colon wall is distended and thin. Three incisions, 2½ inches long, are now made through the skin down to the deep fascia, one parallel to the border of the ribs over the seat of the splenic flexure, another corresponding to this over the hepatic flexure at a slightly lower level, and a third, a transverse incision, at the midline over the stomach. The long sutures are threaded singly into a Peaslee needle, passed successively into the abdomen through the abdominal wound and brought out in the bottom of the skin incisions previously described. First the stomach sutures are passed emerging in the midline incision, the stomach restored to normal position, and the sutures drawn taut, tied and cut short. The three pairs of sutures in the colon are successively passed in the same way, each pair in the three designated loci of the colon being directed to the incision in its corresponding location. All the sutures are drawn taut to straighten out the intestine and make intimate contact between the intestine and the parietal peritoneum, and then tied externally to the fascia in the bottom of the incision and cut short. The three incisions are then closed with a subcuticular catgut suture and sealed with sterile collodion.

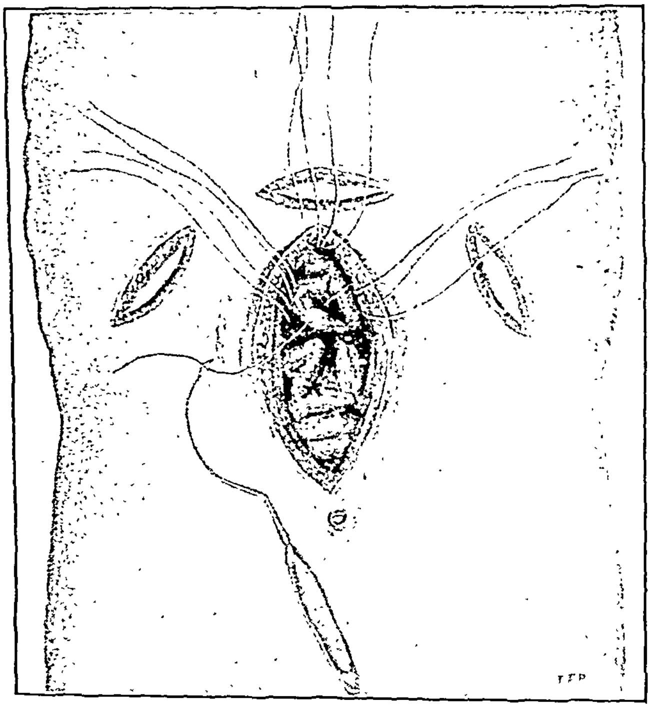

Fig. 3.—The colon has been returned to the abdominal cavity. The Peaslee needle has been threaded with one end of first suture ready for passage through abdominal wall.

It will be observed that the fixation sutures of the stomach and transverse colon are brought out through the same incision. When both organs are to be attached, the fascia in the bottom of the wound is laid bare for half an inch above and below the middle of the wound and the respective sutures passed at the extreme limits of the denuded space, the stomach sutures above and the colon sutures below. The two sutures composing the various pairs are threaded along in the walls of the viscera in the same line and about one-fourth inch apart. I have thought it advisable in some cases to link these sutures together, thus converting them into a figure of eight suture. This distributes and equalizes the tension over a broader area and diminishes the tendency to cut. The abdominal wound is closed in the usual three layer method. Adhesive plaster and bandages are applied moderately tight and the foot of the bed kept elevated from 6 to 18 inches, according to the tolerance of the patient.

REPORT OF CASES

Including the first case already reported, I have subjected, in all, seventeen women to this operation in one or more of its phases and attended with various complications, with fifteen satisfactory recoveries, some of them quite phenomenal, one unsatisfactory, and one death as a direct result of a complication, modification or supplemental procedure. All of them had suffered for years from obstinate constipation, loss of flesh and strength; some of them were broken down neurasthenics; two had ptosed kidneys (one tuberculous), one a ptosed liver, and others displaced uteri and diseased appendages. Diagnosis was made from history and symptoms, palpation and percussion, confirmed in some instances by the roentgen ray. In one or two instances the conditions were discovered on opening the abdominal cavity for diseased uterine appendages and displaced uteri. Four patients were between 20 and 30; nine between 30 and 40; three between 40 and 50, and one, 59.

Nine were housewives; three, stenographers; two, servants; three had no occupation except social duties (two of them were daughters of physicians.)

Suppuration of the sustaining sutures occurred in two cases.

One of these patients was a little, thin, poorly nourished, nervous woman with household cares; she had two little boys, and her husband was a newspaper reporter. The walls of the stomach and the intestine were stretched out and thin. The sutures doubtless pierced the lumen of the intestine or stomach, and infection arose from the contents. I removed about half of them one after another at my office during the three months following the operation. Attachment and support, however, were perfectly maintained. Four years later all organs were found in place, the patient had gained 15 pounds, and she pronounced herself perfectly well and equal to all her duties. She has reported at my office within the past month and confirms all I have said.

The patient that died (Case 12) had a most unusual elongation of the transverse colon, and after all the sustaining sutures had been placed and those at the two flexions drawn taut, the transverse portion looped away down below the umbilicus. It could not be drawn up into place at the middle point without great reduplication and kinking. That seemed to nullify all my work and if possible aggravate the original condition. I therefore resected about 8 inches of the middle section of the transverse colon, making an end-to-end anastomosis. These stitches unfortunately did not hold. There was leakage and in spite of all I could do the patient died of sepsis.

ABSTRACT OF DISCUSSION

Dr. C. A. L. Reed, Cincinnati: In enumerating the causes of visceroptosis, Dr. Goffe failed to mention that which I have found to be the most frequent cause—trauma of the abdomen. A heavy weight falling suddenly on the relaxed abdominal wall is apt to produce severe ptosis which is persistent. Another frequent cause is occupational in character operating in the case of women who are subjected to long standing or heavy lifting under conditions involving relaxation of the abdominal wall. In referring to the different forms of treatment, Dr. Goffe said we must exhaust the resources of the internist. It is perfectly proper to do this when it is shown that the problem is one for the internist, but in a case distinctly impossible of recovery from such treatment why trifle with medicinal means? The gymnastic line of treatment is very good, but the passive treatment is to be regarded as one of constructive and preoperative methods. Assuming once or twice a day the Trendelenburg position, to which Dr. Goffe has referred, with deep massage of the abdominal wall, working everything toward the waist line, is of value in keeping off the ultimate results because it does relieve the mesentery circulation of its most serious complication. Reference has been made to the bacterial evidence which exists, and I would call attention to the researches made within the last year demonstrating an anaphylatoxin germinated by blood stasis. The splendid results obtained from this fixation operation are due to the liberation of the fecal current, restoration of the normal function of the bowel. We have liberated the static blood of the mesenteric circulation and have thereby removed the cause of the anaphylatoxin factors coming from that source.

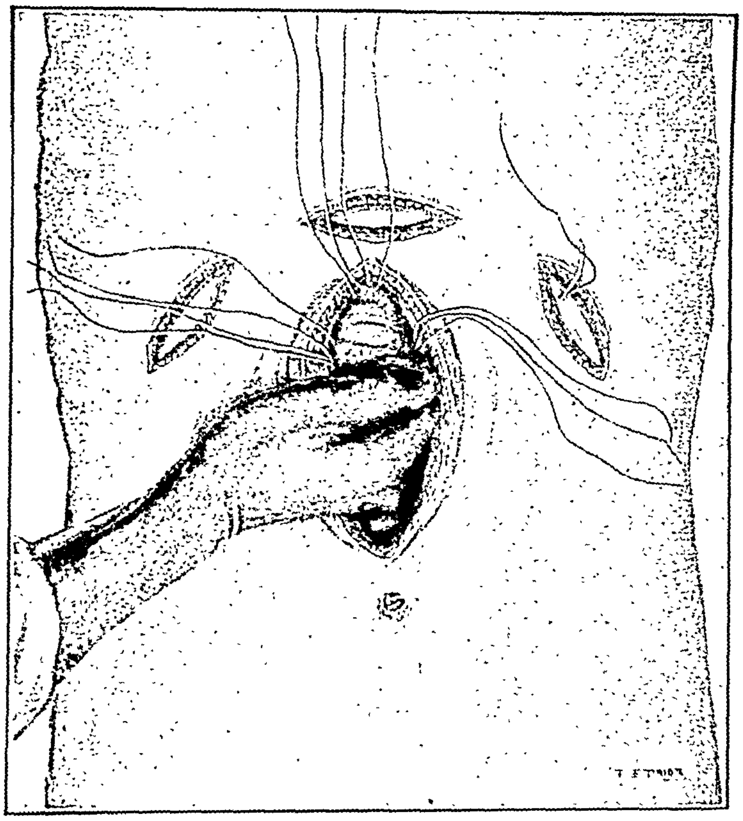

Fig. 4.—Point of Peaslee needle appearing with first suture in abdominal wound. It is unthreaded, the needle is withdrawn, and the same process is repeated with balance of sutures.

Dr. Nathan Rosewater, Cleveland: I have had excellent results in the medical treatment of numbers of these patients, so that they never have required operative interference. I refer to the use of adhesive plaster bandages without operation. The results obtained proved that engorgements into the cranial and thoracic cavities could result from spanchnoptosis and might be restored by attention to the originating cause. Such results in all my cases for the past twenty years make me doubt the necessity for operation, except where all else has failed.

Dr. W. T. Reynolds, Kansas City, Mo.: Dr. Goffe's paper has again brought up the question of what we shall do in these cases of visceroptosis. The modern fluoroscope has made it possible for us to observe these conditions in all their different phases, and one is certainly impressed with the position of the colon (especially the transverse) and the stomach. As one watches the movement of the stomach and the colon he at once questions the advisability of any sort of fixation operation. I believe Rovsing's classification of maternal and virginal visceroptosis is one of the best. In operating on women with large uterine fibroid I have often found the transverse colon lying down near the pubes without giving rise to untoward symptoms. I am convinced that only a small percentage of cases with visceroptosis are ever treated, and those who apply for treatment are of that distinct type, the undernourished. Belts no doubt have their place in the treatment of these cases, but, after all, forced recumbency and feeding with the hope that they will accumulate fat on the inside of the abdominal cavity is most important.

Dr. A. H. Aaron, Buffalo: I have seen a great number of these cases of ptosis and have been impressed with the lack of the tone of the muscles and tissues of the abdominal wall and the contained organs. The abdominal bandage, if properly applied, is curative in the great majority of these cases. You yourself must put the bandage on and see that it relieves the condition as intended, and you must study the cases fluoroscopically at various intervals of time to determine the efficacy of the support. It is desirable to treat the patient constitutionally with rest, abdominal support and forced feeding for a number of weeks, when the tissues will be improved to such an extent that the patient is in better condition for an operation if this is indicated. A greater number of these cases are medical before operation and essentially medical after operation.

Dr. J. Riddle Goffe, New York: I spoke of the gymnastic treatment as prophylactic. I have not found that it does much good as a cure. My experience with the abdominal belt is that in ninety-nine cases out of a hundred the kidney will slip down under it. The patient is then worse off than before. The gentlemen who have spoken of the advantage of the belt apparently have had unusual success with it, but this is not in accord with my experience or with my observation.

Convulsions.—There are two features which, together, cooperate in producing the symptom which we call a "convulsion." One of these we may call the chemical factor; the other the mechanical. The one, the chemical, acts in producing edema of the brain, which so long as there is a sufficient blood supply shows itself in headache, moderate dilatation of the pupils, and other changes which are suggestive of more serious symptoms which are convulsive depending on the amount of blood that reaches the swollen central nervous system. The amount of blood reaching the brain depends on the difference between the intravenous pressure and the intracerebral pressure. As long as the cerebral swelling is not great enough to bring the difference in intravenous and intracerebral pressure too close to zero a convulsion does not occur. Also as long as the intravenous pressure remains enough above the intracerebral pressure to adequately supply the brain with blood, the convulsion will not occur.—*Journal of Laboratory and Clinical Medicine.*

THE USE OF SODIUM BROMID IN ROENTGENOGRAPHY *

E. H. WELD, M.D.
ROCHESTER, MINN.

In the past, various substances have been used as opaque mediums in pyelography. Among such substances may be mentioned bismuth, the colloidal silver solutions (collargol, argyrol, electrargol, cargentos, etc.), and several preparations of silver iodid and thorium. Many of these substances, when retained in the renal pelvis, have a more or less irritating action on the kidneys, as has been demonstrated experimentally by Braasch and Mann, who injected the kidney pelves of sixty-seven dogs, and compared the effects of a variety of solutions. The results of their experiments show that the silver preparations act as foreign bodies, frequently causing multiple foci of necrosis, and that such focal necrosis may also occasionally occur when there is insufficient drainage from a kidney pelvis, even when bland fluids are used. Thorium nitrate in a 15 per cent. solution, as suggested by Burns, caused the least reaction of the various opaque mediums. This medium has been widely used in pyelography, and, until recently was considered the best one available, the greatest objections to it being the chemical difficulties in its preparation and the excessive cost. More recently Cameron has advocated the use of potassium iodid in a 25 per cent. solution, which appears to be fully as opaque to the roentgen ray as thorium; it has the advantage of being easily prepared, and is somewhat less expensive.

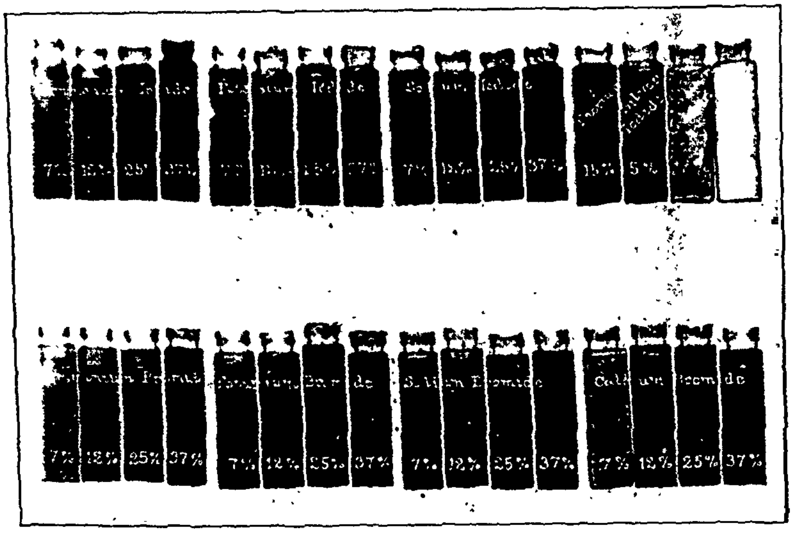

Fig. 1.—Comparison of different solutions; roentgenograms taken in 8 c.c. bottles.

The ideal medium for pyelography should be nontoxic, nonirritating and easily soluble in urine—one that is easily sterilized, that keeps well under all conditions, and is easy to procure at a reasonable cost. In experimenting with various solutions in order to determine their opacity when rayed, we found that the bromids were quite as satisfactory as any of the other solutions, and in many cases it was only necessary to use a 12.5 per cent. solution to obtain a readable pyelogram or cystogram. It would seem that the opacity of various solutions should vary as directly as their atomic weights. However, there is little or no difference in the opacity of the solutions of the same strength, whether bromids or iodids (Fig. 1). Severe reactions have been observed in several patients, when potassium iodid in 25 per cent. solutions was employed. This was evidently due to local irritation. The bromids have not appeared to be so irritating as the iodids. Bromid salts are freely soluble in urine, so that their irritating action is continually lessened by dilution with urine from the time that they are injected. They are excreted very largely by the kidneys, and no deleterious effect on the substance of the kidneys has been noted. The toxic effect that might be produced may be disregarded, because as much as 8 or 10 gm. of the salts have been given by mouth without producing any untoward symptoms, and it is unlikely that there is much absorption in the genito-urinary tract. Probably no sedative effect would be noted.

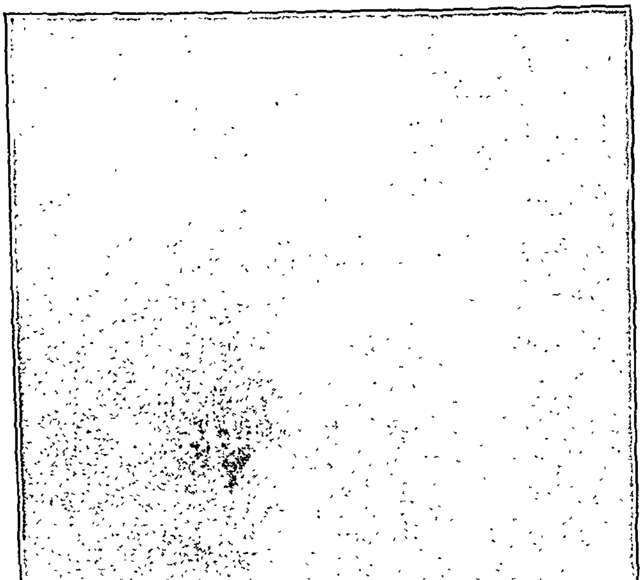

Fig. 2.—Pyelogram with 25 per cent. sodium bromid solution; slightly dilated pelvis; normal calices; lead catheter on left.

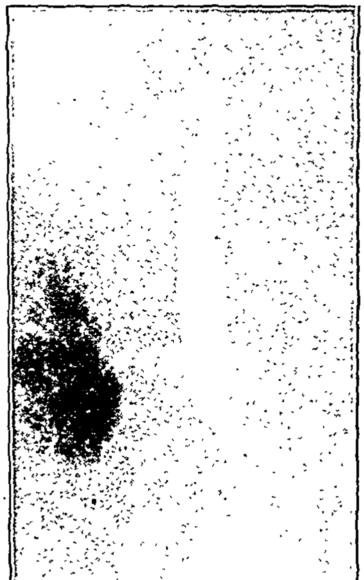

Fig. 3.—Pyelogram with similar solution; marked inflammatory dilatation of calices and ureter.

The opacity appears to be due almost entirely to the bromid radical, as it is shown that when sodium

---

* From the Section of Urology, Mayo Clinic.

chlorid is used, little or no retardation of the roentgen ray is noted. Sodium bromid, apparently, smears over the surface of the ureters, minor calices of the kidneys, and small saccules of an inflammatory bladder even much better than thorium, and for this reason we believe has a distinct advantage over it. Furthermore, the drug is easily obtained, and costs only 75 cents a pound at the present time, whereas potassium iodid costs $4.90 a pound, and thorium, even in a 15 per cent. solution, largely because of the difficulty in its manufacture, costs $2.50 a pound.

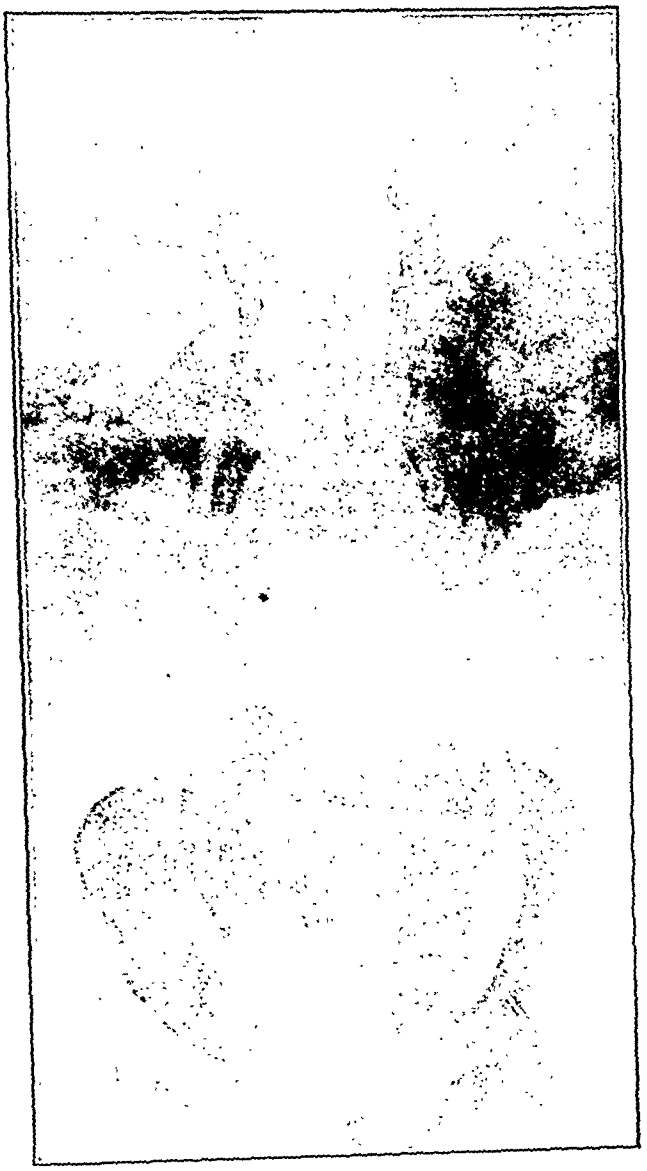

Fig. 4.—Cysto-ureteropyelogram with 25 per cent. sodium bromid solution; bilateral ascending pyelonephro-ureteritis, cystitis and distorted bladder.

We have injected 2 c.c. of 25 per cent. sodium bromid in the ureters of three dogs, in which the ureters were ligated and divided immediately after injection. Six days later, a nephrectomy was performed and a hydronephrotic sac containing approximately half an ounce of fluid was found. Macroscopic and microscopic examinations of these kidneys did not show any irritating effects from the drug. We have used a 12 per cent. solution of sodium bromid in making several cystograms on patients, and a 25 per cent. solution of sodium bromid in making several pyelograms, without noting any injurious effects (Figs. 2, 3 and 4).

Experiments are now under way for the purpose of comparing the effect of thorium, potassium iodid and sodium bromid, when they are retained in kidney pelves, and also for the purpose of studying the gradual development of hydronephrosis after the injection into the kidney pelvis of various opaque solutions. The sodium bromid is easily procured, easily sterilized, and is inexpensive. In our experience sodium bromid in a 25 per cent. solution, has offered advantages as a medium for pyelography as follows:

1. It is a bland solution and does not damage the kidney.
2. It casts a clear shadow, outlining the entire pelvis and ureter as well as, if not better than, other mediums thus far advocated.
3. It is less irritating to the pelvic and vesical mucosa than other mediums.
4. It is the least expensive, and is readily procured.
5. It is very easily prepared, and is readily sterilized by boiling.

AN EFFICIENT SUPPORT FOR SACRO-ILIAC RELAXATION *

W. BARNETT OWEN, M.D.
LOUISVILLE, KY.

The importance of sacro-iliac strain or relaxation in the production of partial invalidism has been recognized for several years. The frequency of occurrence and the persistence of pain and discomfort incident to relaxation of the sacro-iliac joint following childbirth, prolonged illness, and also from excessive pelvic strain and distortion, has necessitated the devising of a more efficient type of support than has hitherto been obtainable, that is, one which can be worn continuously and maintained in the proper position. The greatest difficulty that has beeen experienced in the use of previously devised types of support, including the various belts, braces, etc., has been the maintenance of sufficient continuous support over the sacro-iliac joint.

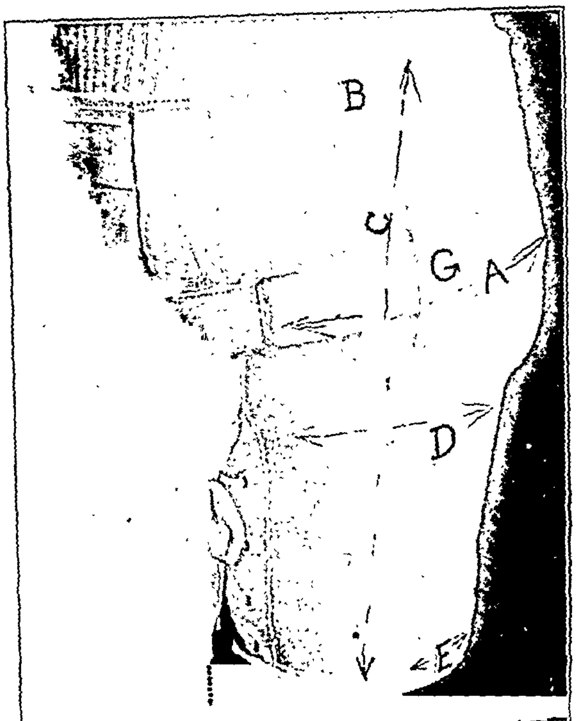

Fig. 1.—Support for sacro-iliac relaxation. Measurements in Figures 1 and 2: *A*, circumference for belt; *B*, circumference of crest; *C*, outside; *D*, circumference of thigh at gluteal fold; *E*, circumference of thigh 5 inches below; *F*, gluteal fold to top; *G*, loops.

---

* Read before the Section on Orthopedic Surgery at the Sixty-Ninth Annual Session of the American Medical Association, Chicago, June, 1918.

While I claim no originality for the type of support herewith exhibited, I have never seen another just like it. However, should other identical devices be in existence, I can recommend them most highly in the treatment of sacro-iliac strain and relaxation.

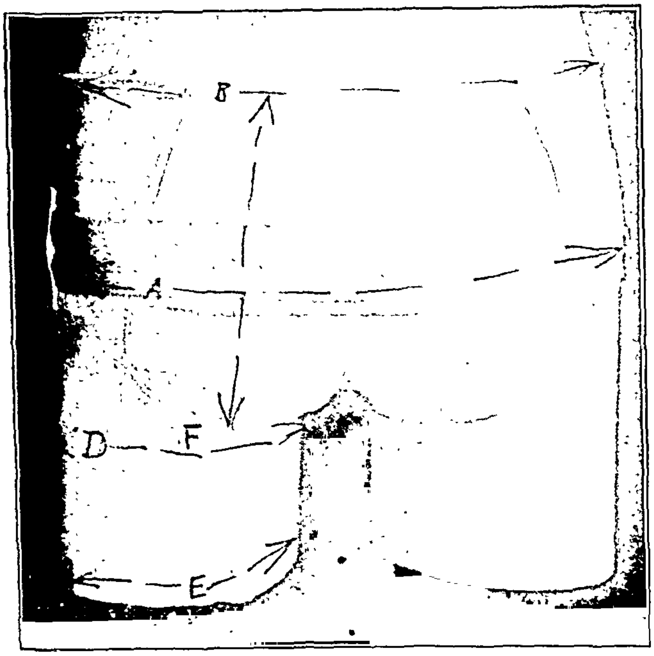

Fig. 2.—Back view of support.

To insure proper results, the device must be maintained in such a position that the lower border is on a line with the greater trochanter and the pubic arch, and at a corresponding level over the sacro-iliac joint. In other words, the support must be maintained as low as possible, and at the same time allow the patient to assume the sitting posture without discomfort. No matter how carefully applied, the ordinary belt will invariably slip upward, and where perineal straps are used to prevent this they cause so much discomfort from pressure on the perineal region that it becomes necessary to loosen them, and the supportive efficiency is thereby lost.

It has been my practice to have the apparatus made of bleached drilling doubled, the fixation skeleton resembling a pair of short pants extending from the crest of the ilium to the middle of the thighs following the gluteal fold, with a loop on each side through which passes a heavy elastic belt 1½ inches wide. The best results will be obtained by having the support fitted directly to the patient before it is completely finished. When this, however, is impossible, the device may be satisfactorily constructed by the measurements indicated in Figures 1 and 2.

I have supervised the application of this particular type of support in more than 200 cases of sacro-iliac relaxation or strain, and the symptoms have been entirely relieved excepting in two instances; but neither of these represented the classical type of sacro-iliac strain.

Case 1.—A woman, aged 35, attempted suicide by taking morphin, and then by jumping from a second story window astride a picket fence. A number of injuries were inflicted, the most serious of which were separation of the left sacro-iliac joint and separation of the pubic articulation. In this instance it was necessary to apply first a double plaster-of-Paris spica with the limbs completely extended and abducted to about 45 degrees. The sacro-iliac support was afterward applied as a convalescent splint and was thoroughly satisfactory.

Case 2.—A man, aged 25, a laborer, who claimed his sacro-iliac strain was due to heavy lifting while performing some work he was not supposed to do but which he had been ordered to execute by his employer—a rich corporation. The supportive device described was applied, and while much benefit resulted he said he could still feel a "slipping motion" of the sacro-iliac joint. Several roentgenograms were taken under attempted pelvic strain, but all the plates in all positions proved negative. The patient insisted on having a surgical operation performed, which I repeatedly refused to do. However, he was later operated on by another surgeon, both sacro-iliac joints being fixed by zigzag wires fastened to pins driven in the opposing bone. The patient claimed that this operation quickly relieved him of all symptoms. I may possibly be mistaken in this case, but it is my firm belief that a satisfactory settlement was the "treatment" most desired from the patient's point of view.

Of more than 200 patients treated for sacro-iliac strain, twenty-four came to my office on crutches.

Case 3.—One man from southern Indiana had been confined to his bed for eight weeks; he was sent to me for examination to determine if anything could be done for his relief. He was barely able to walk on crutches with the assistance of his physician and a brother. Arising from a stooped position or from a chair without help was absolutely impossible. Roentgenoscopy was negative. The pain was localized over the sacro-iliac joint and radiated downward posteriorly. The sacro-iliac support was applied and the man was able to walk immediately without the aid of crutches despite his physical weakness from having been in bed eight weeks. He returned ten days later walking without the aid of a cane or other assistance excepting the sacro-iliac support. He walked so well that I did not recognize him when he came into the office; he sat in a chair and arose several times without assistance before telling me who he was. He said that on the sixth day after application of the device he was able to "plow tobacco." The support was worn continuously day and night.

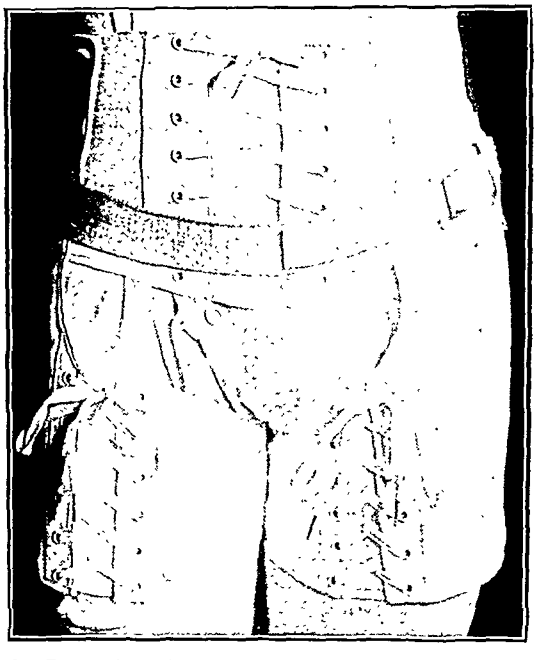

Fig. 3.—Front view of sacro-iliac support with abdominal support.

All the patients coming under my observation for the treatment of sacro-iliac relaxation or strain have been closely followed, and I am certain that the final outcome has been good in all excepting the two atypical cases mentioned.

ABSTRACT OF DISCUSSION

Dr. Fred. J. Gaenslen, Milwaukee: The author has confined his remarks to sacro-iliac relaxation and to means of supporting this joint. The belt which he has devised answers the purpose admirably, though I would suggest that it be fastened in the back to give greater security. The thigh pieces, while efficient in preventing the belt from slipping up, are not always necessary. As a rule, other and simpler means suffice.

Dr. Charles A. Parker, Chicago: Sacro-iliac strain, subluxation or relaxation, is a sort of "bogy man," and when suggested to a patient is dire in its effect on the nervous system. Perhaps there are instances of these sacro-iliac conditions, but these patients can be given a favorable prognosis. This does not, however, relieve us of responsibility for the care of lower-back troubles, and the necessity for most conscientious care in the consideration of these complaints. We must not overlook the occasional static troubles of the back. The more thoroughly we investigate the less frequently shall we have to fall back on such equivocal terms in lieu of definite pathologic entities.

In the treatment the psychology of back pain is often not sufficiently appreciated; for the alarm that goes with a pain in the back, with the ever present specter of increasing disability and final paralysis, heritage of false teaching and superstition, is enough to upset, and often does upset, an otherwise stable nervous system, when the real trouble would be considered insignificant if it occurred with equal intensity in some other supposedly less vital region. What the effect may be on an already depleted nervous system is painful to contemplate. It is in these latter individuals that the devotees of blue lights and pink bands and red lights and hot air accomplish their most wonderful cures. Patients of more stable character can be shown that with an apparently normal anatomy, with no evidence of tuberculosis, cancer or other serious conditions present, their chances for steady improvement and ultimate recovery are great. Relief by this means, while usually not so startling as that by the more spectacular method, is often very striking and is apt to be increasingly efficient. These cases must be treated by such means as their true pathology suggests.

Dr. J. P. Lord, Omaha: I agree with everything that has been said, except that I am not so much disposed to make light of the infrequency of this condition. There are cases that will continue to give you trouble until you secure other supports for the sacro-iliac joints than by putting bands about the pelvis. In the severer cases, and those failing to be relieved by ordinary supporting bands, it has been my practice to add to the pelvic metal band a support for the lower part of the chest, so as to get rid of the adverse strain produced by movements of the spine, which is so prone to disturb the sacro-iliac joint. Since I have been adding a "second story" to Osgood's apparatus I have secured a greater amount of relief.

Dr. John L. Porter, Chicago: When it comes to sacro-iliac relaxation I am the worst skeptic that ever was. In twenty years I have seen just two sacro-iliac joints that some one could demonstrate to me were relaxed sufficiently to show movement. Both were in pregnant women. I have never had any one demonstrate to me a sacro-iliac joint with motion in it in a normal individual who had not had some pathologic or physiologic process (such as pregnancy) to produce relaxation of these joints.

Dr. Ethan H. Smith, San Francisco: Within the last two years I have treated nearly three hundred cases that appeared to have relaxation of the sacro-iliac joint. I think that this term is an undeserved slander on that articulation. These cases will be found to have a tilt of the pelvis in one direction or the other, a tilt of the lumbar spine, with relaxation of the lumbar muscles on one side and a contraction of those on the opposing side. In such cases as need bolstering up I have used a modification of the corset devised by Dr. Robert W. Lovett, with a great deal of satisfaction. In the last two months I have assisted in the examination of several thousand men for the Army. In certain contingents I found that 10 per cent., and in other contingents 30 per cent., presented a pelvic tilt, with contraction of the muscles on one side and relaxation of those on the opposing side. I also found that two-thirds of those that presented this condition did not know that they had it, and had no pain. I found many of these cases among employees of the Union Iron Works, many of whom have been drafted; and in private practice I found them among saleswomen, especially those handling heavy garments in the suit and coat departments of large stores. It was also common among persons who habitually stand on one foot, and in those who habitually carry little babies on one arm. I have come to the conclusion that in those cases in which we find no pain we do not diagnose a sacro-iliac joint disturbance, while in those who have pain (and there are three times as many that are painless as those that come with pain) the condition is recognized. Dr. Owen's apparatus looks as if it were very efficient. I think that it will have a good effect on these cases, but I still disbelieve in sacro-iliac relaxation.

Dr. W. Barnett Owen, Louisville, Ky.: I expected exactly what I got; but I still maintain that when you have a patient come to you with extreme pain over the sacro-iliac joint, radiating down the thigh, and that patient has had every form of treatment from electricity to antirheumatics, with no relief, one should give him a support. Dr. Porter mentioned two cases that he had seen in which there was slipping. I only mentioned that one patient said he could feel slipping. Always roentgenographic and otherwise careful examination was made, and in every case all symptoms, except pain in the sacro-iliac region aggravated by attempted strain, were absent. It is immaterial whether you call the condition sacro-iliac relaxation or neurosis. The patient comes for relief. If a proper support will relieve him, give it to him, and select a name later. Nourishment is not kept from babies until they are named.

DERMATITIS LYCOPERSICUM ESCULENTUM (TOMATO PLANT) *

EVERETT S. LAIN, M.D.
OKLAHOMA CITY

When certain plants are brought into proximity or actual contact with the skin of certain individuals, more or less reaction follows. The skins of some persons, however, are not appreciably inflamed even from contact with the most commonly known poisonous plants.

No writer on this subject, so far as I know, has yet attempted to enumerate or classify all such poisonous plants. Some authors do not mention more than a few of the well known plants, such as the poison ivy, the sumac, the wild rose, and the nettle, with their several offending members.

Various other names are continually being added to the list of so-called poisonous plants, namely, plants that are capable of producing a dermatitis venenata on the susceptible skin of certain persons.

ETIOLOGIC FACTORS

A plant that is capable of producing a dermatitis in certain sensitized individuals appears to be less infectious at certain seasons of the year or, in other words, at certain stages of its growth. This is due to the fact that only certain parts of the plant, such as its pollen, hairs, thistles or its expressed juices are poisonous. Botanists have asserted that climatic conditions may favor or retard the development of this poisonous element.

---

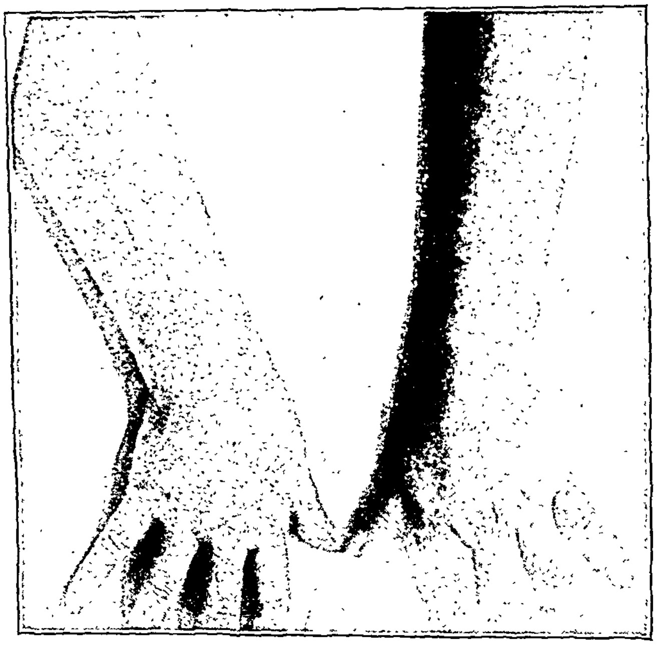
* Read before the Section on Dermatology at the Sixty-Ninth Annual Session of the Americal Medical Association, Chicago, June, 1918.

Persons who are susceptible to this form of dermatitis are spoken of as possessing an idiosyncrasy or a special sensitization for this particular plant. The fact that the same individual is not always affected when coming into contact with the same plant has been theorized on by the French school[1] as bearing a relation to the normal or perverted condition of the visceral organs. Walsh[2] states that it may be due to a temporary lack of a full supply of blood to that locality on which the dermatitis develops. American histopathologists seem more inclined to call it an anaphylactic reaction of a sensitized condition which that persons bears toward that particular chemical or protein poison.

AUTHOR'S OBSERVATIONS

Having practiced in the South, where a large variety of vegetation grows luxuriantly, I have had an opportunity to observe different herbs, plants or vines that are capable of producing this form of dermatitis. During the past several years I have frequently noticed on the hands and sometimes the faces of hucksters and gardeners a form of dermatitis for which it has been difficult to account, other than on the basis that it had been caused by some common garden vegetable.

In the summer of 1916, after having carefully noted the history and development of several of these cases, my attention was directed especially to the ordinary tomato plant, which is found in nearly every garden in its season. Since that time, I have noted several cases which seem to bear a positive relation to the gathering of tomatoes from rank and dewy-laden vines.



Dermatitis venenata in Case 1. Second attack in the same patient, each time the lesions appearing within a few hours after gathering tomatoes from rank, dewy-laden plants.

At first it seemed preposterous that the plant on which the tomato grew should be capable of doing harm even to the most sensitive of human skins. I made a brief search of textbooks and the literature on skin eruptions which might be caused by plants. I found many plants mentioned by various authors, yet I did not find a single reference to the tomato plant.

I then wrote to the reference department of the American Medical Association and received a reply that it had only one article indexed—a French abstract—that mentioned the tomato plant. I looked up the botany and classification of the tomato plant. It then occurred to me that this plant was a very probable etiologic factor in several of my cases of dermatitis venenata, which had been previously recorded as "cause unknown."

HISTORY AND CLASSIFICATION

After reviewing the history and classification of this vegetable, I find that the name "tomato" is derived from a Spanish word *tamate,* which was given this plant by the Spanish people of South America, of which countries it is a native. It is botanically known by its Latin name—*Lycopersicum esculentum.* This name, meaning "wolf peach," gives us a brief insight as to the opinion of the South Americans toward this plant, which opinion prevailed until after it was introduced into both Europe and North America. For several centuries it was considered, even by the Europeans, as a poison and was grown only as a garden ornament, which they called "love apples." Not until about the middle of the nineteenth century did this plant become generally cultivated as one of our most harmless and luscious vegetables.

The tomato plant belongs to the *Solanaceae* group and the family of nightshades. One well known member is recalled as the deadly nightshade or belladonna, meaning, "beautiful lady," relating to the practice at one time of certain Italian ladies of making their eyes beautiful by the application of certain parts of this plant. Belonging to the same family, we find the jimpson weed, the horse nettle, red pepper, and the egg plant. Some of these plants, we recall, are a most common cause for an urticaria, either from local contact or internal ingestion.

Bailey[3] states that nearly all of the *Solanaceae* group contain poisonous narcotic alkaloids or glucosids which may be converted into a certain amount of hydrocyanic acid. According to Pammel,[4] the tomato plant contains saponin among other active elements. Physiologic chemists state that saponin is a poisonous glucosid, soluble in water, and becomes a violent irritant when applied in soluble form to the mucous membranes or delicate epithelial tissues. Whether this will account for the dermatitis which this plant appears capable of producing, I am unable to say.

APPEARANCE OF THE ERUPTION

This type of dermatitis venenata that I have observed, is not materially different from that produced by many other poisonous plants, such as the so-called blood weed, or a mild degree of the *Rhus toxicodendron.* The few cases which I have noted during the past two summers have occurred on the dorsum of the hands, wrists and both surfaces of the forearms. The eruption most frequently begins as a mild stinging or itching sensation, followed in a few hours by an erythema on the surface of the skin which has been exposed. The area has no sharp lines of demarcation, such as is sometimes present in *Rhus* poisoning. On this erythema there develop miliary, discrete papules which soon become vesicular. Few of these vesicles reach the size which is observed in many other forms of dermatitis venenata. It is most frequently limited to the surfaces which have been in friction contact with the so-called hairs, and probably the bruised leaves or limbs of the plant.

[3] Bailey, L. H.: Encyclopedia of Horticulture, **4**, 1931.

[4] Pammel, L. H.: Manual of Poisonous Plants, **1**, 62-63.

All of these patients gave a history of having exposed their hands and forearms among rank vines in the morning hours while the plants were yet laden with dew. This moist condition seems also to be a predisposing factor in other infectious plants. A dermatitis due to this plant is not an everyday incident, even in the practice of those in the more rural districts. Nor is it probable that the same plant is equally as infectious in every particular locality or season in which it is grown. Therefore, within two seasons I have noted less than a dozen cases bearing a positive etiology.

I will briefly report only two cases which are fairly representative of each of the others.

REPORT OF CASES

Case 1.—Mrs. C., aged 45, who had a thin, clear and tender skin, and was in good health, consulted me for an eruption on the backs of both hands and covering both forearms almost to the elbows. She had not been outside of the house except in the garden to pick tomatoes the previous morning. A prickling, itching eruption had begun within a few hours after gathering her tomatoes. At the time of my examination the eruption had the usual clinical symptoms of a mild dermatitis venenata. I made inquiry in regard to all other possible sources of infection or the application of drugs with negative results. I went out and inspected her garden. This garden presented an unusual absence of weeds of all kinds. On inspecting the tomato plants I found them large, rank, thrifty plants, with no evidence of infecting insects, such as the blister bug. I noted, however, that the limbs were bruised in places, also heavily covered with the so-called downy plant hairs.

Case 2.—Mrs. G., aged 30, who had a blond, fair, tender and well-kept skin, consulted me for an eruption on the dorsum of the hands and arms to the elbows. The eruption presented the usual and clear differential marks of a mild dermatitis venenata. I made inquiry in regard to her whereabouts the previous few days, also particularly concerning the application of any hand or skin lotions, but with negative results. On inquiry in regard to contact with plants, she said she had gathered her tomatoes on the previous morning. The eruption, or the beginning sensations, had begun late the same day. This lady also recalled having had a similar eruption the previous summer, when she had gathered her tomatoes without wearing gloves. I did not go out to inspect this garden, but learned that her garden was free of other possible infecting plants. Also, her tomato plants were considered the finest in the neighborhood.

CONCLUSIONS

I realize that I shall appear as rather premature in presenting any definite conclusions on so few cases observed. Also, it may be reasoned that, if the tomato plant is poisonous to certain individuals, it seems strikingly strange that some dermatologist has not heretofore observed and reported it.

To the first accusation, I plead guilty. To the second, I have only to say that, after seeing these few cases which have a positive etiologic history; after noting the close botanical and chemical relationship between this and other known poisonous and infectious plants; also, after having studied its branches under magnified power, I am fully convinced that the tomato plant is and has been an etiologic factor in some of my cases of dermatitis venenata.

It may be that such cases are extremely rare or that they are confined to certain soils or seasons.

Finally, it is neither my ambition nor my opinion that another new name should be added to an already well known disease—dermatitis venenata. I only trust that this report may cause other dermatologists to observe and that eventually we may learn the full possibilities for harm which may lurk in this common vegetable.

ABSTRACT OF DISCUSSION

Dr. Arthur W. Stillians, Chicago: We must thank Dr. Lain for adding another to the many known causes of dermatitis venenata. The etiology of these cases is so often difficult to determine that there must still be unknown factors, and the discoverer of one of them is a benefactor to dermatology.

Dr. Frank Waugh, Chicago: A patient I have had under observation had this trouble every fall while working in a florist's shop when chrysanthemums were in full bloom. I do not remember having heard of a dermatitis venenata due to the bloom of the chrysanthemum, which in this case proved to be the etiologic factor.

Dr. Ernest L. McEwen, Chicago: Inasmuch as this is one of the first cases reported of dermatitis due to the tomato, I think we should congratulate Dr. Lain that he does not contemplate coining a new name.

Dr. Frederick G. Harris, Chicago: I would like to ask Dr. Lain if he has eliminated the possibility of the trouble being due to some insecticide. This might well occur in picking vegetables that had been sprayed with arsenic or other solution.

Dr. David Lieberthal, Chicago: I should like to know if Dr. Lain noticed a recurrence of the dermatitis after a repetition of picking tomatoes. In that case the cause would be established.

Dr. Richard L. Sutton, Kansas City, Mo.: Dr. Lain's paper is of great interest, for it gives us a new plant dermatitis. I wish to record another new variety of industrial dermatitis, one which might be designated as "cactus dermatitis." It was first described to me by Dr. George P. Lingenfelter of Denver, and is a comparatively common disorder in the arid regions of the west. The disease develops as a result of the lesions caused by the small, splintered spicules that break off the stalks of cactus plants, and the majority of the victims are gasoline tractor drivers. The wounds, which usually are confined to the patient's arms and legs, frequently become infected and severe ulceration oftentimes ensues.

Dr. Robert G. Washburn, Milwaukee: About a year ago I had the opportunity of observing a case of dermatitis of the hands in a woman, resulting from the handling of the tomato during the process of preserving. This would seem to indicate the presence of the poison in the juices as well as in the stems of the plant and would eliminate any question of poison from insects or insecticides.

Dr. Harold N. Cole, Cleveland: I was wondering if the dermatitis resulted from the sharp spicules of the tomato vine, which are often so plentiful on these plants.

Dr. James Herbert Mitchell, Chicago: I would like to ask if transplanting the young tomato plants in the garden is likely to produce this result. Recently I have seen a number of cases of dermatitis venenata which occurred in men who were doing amateur gardening, and close questioning failed to elicit any contributory cause.

Dr. William Allen Pusey, Chicago: Dr. Lain's paper was extremely timely and I congratulate him for having given us so much information on this subject. I sympathize with him in the manifest inability to answer some of the unanswerable questions that have been put to him. Nevertheless, I have no doubt he is correct in attributing his cases to the tomato. He seems to have made out an undoubted case and to have done all that possibly could be done to establish it. The determination of the local causes of many of the cases of dermatitis that we see is a difficult matter. It requires ingenuity and much of the sort of patience that he has exhibited.

Dr. Everett S. Lain, Oklahoma City: Dr. Pusey has come to my aid and suggested the impossibility of replying to all of your questions. As regards the chrysanthemum mentioned by Dr. Waugh, if he will look up the literature on poisonous plants he will find that the chyrsanthemum belongs to the poisonous group, as do also the geranium and the nightshade. As regards eruption from insects, I examined the plants closely for the blister bug, the insect which produces eruptions most frequently in the South, but found none. Most insects which may cause a dermatitis are very well known. I found none of these on any of the plants examined. As regards a second infection, I have been observing this plant for two seasons only. In this time I have seen but one second infection. This was the lady whose photograph I have shown. As regards the infecting parts, I have suggested the hairs of the plant or possibly the glucosid, which is soluble in water; also that some friction seems necessary for the infection to take place. As regards the transplanting of tomato plants in the garden, I have never seen a case caused by such handling. I have experimented on several persons who were not, however, susceptible to the common poisonous plants, without a successful inoculation. Therefore, I am quite sure that most people are immune, or are not susceptible to infection from this plant.

THE USE AND ABUSE OF PITUITARY EXTRACT *

GEORGE W. KOSMAK, M.D.
Attending Surgeon, Lying-In Hospital.
NEW YORK

No addition to the obstetric armamentarium during recent years has created so much attention and interest as the introduction of the solution of the active principles of the posterior lobe of the pituitary body, or hypophysis cerebri. Dale described its action on the uterine muscle in 1906, and later experiments by Frankl-Hochwart and Fröhlich showed that pituitary extract caused marked contraction of the uterus in pregnant animals. It was not until Blair Bell in 1909 employed these experimental results in practice that the therapeutic employment of the drug was begun. He used it in cases of postpartum hemorrhage and to reduce the bleeding in placenta praevia and cesarean section. The physiologic basis for the employment of the drug rests on the knowledge of its stimulating effect on all unstriped muscle tissues, including those of the blood vessels, intestine and bladder as well as the uterus, although it seems to have a more selective action on the latter. At first regarded with doubt, the use of the drug increased by leaps and bounds aided by the supposedly favorable results reported by many clinical observers and by the clever and often unrestricted advertising methods of its manufacturers. Most of the marketed extracts are prepared from the posterior lobe and a few from the whole gland of slaughtered cattle. Different manufacturers employed each their own device in labeling the preparation, and although at first there was believed to be little difference in the activity of these, clinical trials showed that some were more reliable than others. The term "pituitrin" came to be the most widely employed and was soon extended to include all the others notwithstanding the efforts of the competing manufacturers to limit such distinctions. Recently one of the latter firms concluded that it would be advisable to limit the application of its preparation in certain classes of cases and has developed two strengths of pituitary extract, one for general surgical use and the other intended for obstetric cases. This seems to me a confession of the necessity for adopting a more definite standard.

The literature on the use of the extract of the hypophysis is now so extensive and the drug has been so widely employed that it would appear profitable to come to some definite estimate of its value, especially as the many favorable reports about its use are counterbalanced by those of a more unfavorable character that are continually creeping into the literature on the subject. On the one hand we find enthusiasts who apparently see no limitations in the scope of its employment; on the other hand are those who find that great caution should be exercised in its use. It seems most desirable that a definite middle ground be established along which such indications can be formulated as will impress any one who is inclined to employ the drug in a given case with the necessity for a thorough knowledge and appreciation of its effects.

The hypophysis extract has now been the subject of clinical observation for a sufficient length of time to warrant such determination as to its value. Many of its enthusiastic advocates report series of cases, including in the field of application the relief of almost any condition depending on the contractile stimulation of unstriped muscle fibers. The fulsome praise of these observers has been even more pronounced and, shall we say, daring, than the fervid claims that the manufacturers of the product allowed themselves in the advertising pages of the medical journals. In this category may be placed the exaggerated and dangerous claim that "the use of the drug is remarkably free from danger even when given in enormous doses." This estimate of the value of pituitary extract was published in 1914, but fortunately the sentiment with reference to such assumed harmlessness has undergone a change, and more recent observers have modified and restricted the field of application and the indications for the use of hypophysial extracts. It was soon realized, among other things, that no satisfactory standard existed for measuring the dosage of the drug, and it seems most essential that the strength of the solution used be more or less definitely known. A "physiologically standardized preparation," labeled as such by manufacturers, is a distinction of little account because the potency of the drug in a physiologic sense probably varies with the species of animal from which the raw materials are obtained, and perhaps even with the season during which the animal was slaughtered. In this connection we may recall the fact that the thyroid gland of animals is known to be subject to such variations, and this probably applies to other endocrine structures. The blood pressure method and observations on the isolated guinea-pig uterus have been largely employed, and the official standard for the United States Pharmacopeia is by comparison with the effects of histamin, a substance isolated from ergot and due to the bacterial decomposition of histidin.

Notwithstanding that considerable work has been done with these methods, impartial investigators find much to criticize in their application and do not regard them as entirely reliable for accurate standardization. It has been shown, for example, that other organic substances stimulate the isolated uterine muscle so that the fact that pituitary extract exerts an effect on the excised uterine muscle and also on the gravid uterus may perhaps be merely a coincidence. It is known, moreover, that various oxytocic substances

---

* Read before the Section on Obstetrics, Gynecology and Abdominal Surgery at the Sixty-Ninth Annual Session of the American Medical Association, Chicago, June, 1918.

react on all smooth muscle tissue, including the arteries and small veins, as well as the uterus. The action of pituitary extracts on smooth muscle thus brings about increased blood pressure and therefore points to a more satisfactory reaction than can be secured by the other methods referred to.

INDICATIONS FOR USE OF PITUITARY EXTRACT

The indications for the use of pituitary extracts in obstetric practice may be said to be fairly well established, and, employed in a conservative manner, its use should be limited to conditions of simple uterine inertia in which no obstruction to the passage of the child exists either in the cervix or in the bony pelvis. Moreover, the patient must not be in a condition of exhaustion. Its narrower field in the induction of labor with or without other means is now largely given up, and its employment to stimulate labor pains in such malpositions as occiput posterior and face presentations is likewise regarded in a doubtful light. If we accept the indications just stated, the many other recommendations fall aside and it is in this larger class of labor cases that most of the trouble results from the indiscriminate use of the drug. The bad effects vary from laceration of the cervix and perineum to complete rupture of the uterus. In addition, the possibility of postpartum hemorrhage must be guarded against, and likewise a possible asphyxiating effect on the child must be recognized.

A sufficient number of cases that demonstrate the unfavorable effects from the use of pituitary extract have now been reported in the literature, and any additions to the list are merely in the nature of confirmations. My personal experience with the drug in hospital and private practice dates back a number of years. Although somewhat apprehensive of its value, I was led to employ it, and the result of my observations failed to convince me that its use is not attended with considerable danger. This opinion is also based on the result of experiences with the drug in the hands of others in cases seen in consultation, or that were referred to the Lying-In Hospital. It seems to me a duty to disseminate knowledge tending to caution a practitioner in attendance in any given case who is about to resort, merely for the purpose of shortening a labor, to a method that recommends itself because of its apparent simplicity and yet is fraught with great danger unless employed under the strictest indications.

One or two typical examples of a considerable number of cases that have come under my personal observations will serve to explain my position with reference to the use of pituitary extract. The first is a case of fetal asphyxia:

> Mrs. P. L., admitted to the Misercordia Hospital in May, 1916, had a moderate toxemia of pregnancy for which labor was induced at term. Slow dilatation was made with bags; labor pains were ineffective; there was nonengagement of the head without pelvic contraction. Extraperitoneal cesarean section was decided on as the only satisfactory method of delivery. The house physician was directed to give 1 c.c. of pituitary extract after the abdominal incision had been made, as I had been doing in recent cases, but it was found that it had been given in error before the incision was begun. When the uterus was exposed it was found to have contracted so firmly around the head of the child that considerable force was needed to extract the head with the forceps, resulting in a tearing of the sutures and entry of the uterine contents into the general peritoneal cavity. The child was deeply asyphyxiated and failed to respond to any efforts at resuscitation.

In this instance it is fair to assume that the extreme contraction of a tonic uterus following the too early application of pituitary extract resulted in complete obstruction of the fetal circulation, as the fetal heart was quite normal before the operation was begun.

I have used pituitary extract in a number of other cases of cesarean section as an oxytocic and have been disappointed with the result. Either the uterus failed to contract promptly after the delivery of the child, or severe postpartum hemorrhage with relaxation occurred before the patient left the operating table. At the Lying-In Hospital we have ordinarily injected 40 minims of an ergot preparation in cesarean cases before operation, and I am satisfied that this is a more effective agent for the purpose, being more certain in its effects and less likely to be followed by subsequent relaxation. I have also employed the pituitary extracts in several primiparas in whom labor pains were weak; and although strengthened for a time after the use of 5 or 10 minim doses, there was not sufficient progress to warrant placing much reliance on the drug in cases of this character. One instance of fetal death which could be attributed directly to a prolonged labor and excessive use of pituitary extract occurred in a patient admitted to the Lying-In Hospital:

> The patient, a primipara, was given three successive doses of 1 c.c. each by her attendant because of apparent inertia, and on admission to the hospital was in a very much exhausted condition with the head moderately well engaged and the fetal heart not audible. The uterus was in a state of tonic contraction, and examination revealed the presence of a well-marked Bandl's ring, the cervix being almost fully dilated with the membranes ruptured. Under the circumstances a craniotomy was indicated and completed with a moderate laceration of the edematous vulvar outlet.

In this instance pituitary extract was contraindicated by the lack of sufficient engagement of the head and an already exhausted patient. The physician who attended the woman was present during the operation and, I feel, had firmly impressed on him the dangers attending the indiscriminate use of this drug.

Such instances might be multiplied by any one in active hospital service and serve to make one very doubtful of the advisability of recommending this drug to the hurried general practitioner. The shortening of labor may save time for the attendant, but it is certainly at the expense of the patient. The dilatation of the soft parts preliminary to the delivery of the child must be slow and gradually produced, and where this process is halted at any time during the labor, it should not be accelerated by the administration of a drug that often produces tumultuous contractions with rapid expulsion of the fetus and consequent extreme laceration of the soft parts. No one would think of applying the forceps to a head unengaged or with a moderately dilated cervix, and yet in reality the danger is no greater.

We can safely dismiss the contention that pituitary extract renders the forceps unnecessary. When the head is engaged and there are no other contraindications to its use, pituitary extract may stimulate the uterus sufficiently to drive the head down to a lower level; but in nine cases out of ten, the process stops at this point, and forceps are needed anyway. Moreover, a rapid extraction may be called for in advance of this time because of the effect of the more rapidly succeeding contractions on the fetal heart. The only cases in which forceps might be avoided would be those in which the fetal head is not well engaged and in which the soft parts or the pelvic brim do not interpose any obstacle to the descent; but even here we find that other means of instituting better pains are equally effective and less dangerous. As for its effectiveness in postpartum hemorrhage, I am yet to be convinced that its value is of anything more than a temporary character, giving merely an opportunity for a more reliable oxytocic like ergot to become effective. I have, however, employed it with good results in cases of incomplete abortion when curettage of the retained secundines is undertaken. In these cases the uterus contracts satisfactorily, and undue bleeding is prevented.

The foregoing remarks might lead one to regard me as a pessimist in my attitude toward pituitary extract; but I am less pessimisitic about the drug than the possibility of ever getting the profession to use it properly. I firmly believe that in a restricted class of cases, as already noted, pituitary extract is of value; but every means should be taken to combat the unfortunately indiscriminate employment of the drug. We all know the bad effects, and yet pituitary extract is being used in increasing measure. Granting that it is a valuable therapeutic addition, no one is justified in saying that it is harmless; for in every case in which it is employed, the indications must be carefully formulated before its injection. Moreover, the usually accepted dose of 1 c.c. is too large, and a trial dose of ⅓ c.c., or 5 minims, followed at intervals of an hour with one or two further doses is a preferable method of administration. If the natural forces of labor are unable to expel the child without assistance, it seems to me that their stimulation by the use of pituitary extract is not quite logical; for the resistance if present can better be overcome by forces from below than by forces from above. I make this statement advisedly because I fully admit that in the latter case, by which we mean application of the forceps, equally developed skill and judgment must prevail. The proper preliminary preparation of the patient for her labor, the avoidance of exhaustion by the administration of opiates, postural treatment and other well tried and safe procedures, together with a maximal degree of patience on the part of both mother and attendant, will do more to reduce the number of forceps deliveries or at least the difficult ones, than the means for stimulating uterine contractions depending on the indiscriminate use of hypophysial extracts. When the fetal head refuses to pass beyond the perineal floor, and caput succedaneum with a rigid, edematous outlet supervenes, why not complete the labor by a low forceps operation, which is certain in its results and completely under the control of the operator?

EMPLOYMENT IN OTHER THAN OBSTETRIC CONDITIONS

As for the use of pituitary extract in other than obstetric conditions, little need be said. It has been widely recommended for the relief of tympanites, but in several postoperative cases I found little effect from its use. Neither is it of any particular value as a substitute for the catheter. I am convinced that more cases of postoperative cystitis result from the retention of residual urine than from the proper employment of the catheter. I have had some very good results from the use of pituitary extract in cases of hemorrhage from the nonpregnant uterus, such as menorrhagia in young girls and in older women presenting small fibroids or adnexal lesions resulting in hyperemia. Here the regular administration during the flow has given excellent temporary results until other measures could be applied.

CONCLUSION

I may summarize my estimate of pituitary extract by describing it as a valuable addition to our therapeutic resources, but one which must be used with great caution, particularly in obstetric cases. Here it is safe only in cases of simple uterine inertia, particularly in multiparas, when there is no obstruction to the passage of the child, no exhaustion, and the presenting part engaged. It should be used in doses of not over 5 minims at a time, repeated only when the effect of the previous dose has worn off. For the induction of labor, or as an accepted substitute for the forceps, it would be best not to consider pituitary extract. Properly used under proper indications, the extract of the hypophysis has a distinct place and value. Indiscriminate and improper use will only tend to relegate a good therapeutic medium to the discard.

23 East Ninety-Third Street.

ABSTRACT OF DISCUSSION

Dr. J. B. DeLee, Chicago: I was one of the first to oppose the use of pituitary extract in labor. Further experience of my own and watching the work of others has confirmed the opinion I expressed many years ago, and has also increased my desire to emphasize the importance of the general practitioner's avoiding the use of pituitary extract in his labor cases. Pituitary extract is like a scalpel; good results are obtained with the scalpel, bad ones, too; but pituitary extract is worse than the scalpel; it is like one of those double-edged bistouries—it cuts both ways, and sometimes in the direction least desired. L. G. McNeile collected sixteen cases of rupture of the uterus from pituitary extract. I know of four others. All happened in the city of Chicago and have not been published. Laceration of the cervix is a complication the importance of which is being recognized more and more. It is nearly always caused if pituitary extract is used before the cervix is dilated. Lacerations of the perineum have always been given a great deal of dignity. They, too, are increased by the use of pituitary extract. Pituitary extract is used so indiscriminately by the medical profession that something ought to be done other than the modest complaints and warnings issued in journals. The subject of the endocrinal relations is still theoretical, but I think clinical experience will give many instances that will prove disturbances of the action of the glands of internal secretion of the fetus. Many children are born dead with the symptoms of asphyxia after the administration of pituitary extract, and the death can hardly be explained by an asphyxia caused by the contraction of the uterus produced by pituitary extract. I used to give pituitary extract before cesarean section, but now give it after the child has left the uterus. I also lived through an experience of spasmodic contraction of the uterus during cesarean section, rendering delivery of the child very difficult. In cesarean section, I give pituitary extract as soon as the child has been extracted from the uterus. I inject one ampule of pituitary extract into the deltoid muscle. I think it makes little difference whose extract is used. If the uterus does not contract promptly, it is also injected with one ampule in two or three spots. I do not give pituitary extract in cesarean section cases after the sutures have been put in. In my opinion, some of the cases of peritonitis following cesarean section and some cases of hemorrhage following cesarean section are due to the use of pituitary extract after the uterus has been sutured. We do not use pituitary extract to produce intestinal action after cesarean sections. I have used a great deal of pituitary extract to stimulate the bladder to spontaneous urination with no results. Pituitary extract seems to have a hemostatic effect besides its effect on the uterus. I have used it occasionally in the hemorrhages of the new-born without success. There are cases of *primary inertia* of the uterus. In these cases, with or without rupture of the bag of waters, pituitary extract will do good; but remember that it is a two-edged knife. When I use it I study the indications with special care; the pelvis for contraction, the cervix for unusual rigidity, the child for abnormal position. A careful investigation of all the attending circumstances is required to enable one to make a proper diagnosis and to place the indication for pituitary extract. The greatest care must be exercised, and I give the extract myself. I have a can of ether at hand for immediate use when indicated. The reason for such extraordinary care was my experience in a case of occipitoposterior position and inertia of the uterus lasting nearly three days, with rise of temperature, showing that the patient was beginning to suffer from infection, in which case it was very desirable to empty the uterus without vaginal examination and without the use of instruments or bags. Three drops of pituitary extract were administered, and produced such a tetanic contraction of the uterus that the woman almost went wild with pain until I could anesthetize her. This woman had an idiosyncrasy to the pituitary extract. Pituitary extract is occasionally useful when, having changed a face to an occipital presentation, strong pains are needed to force the occiput down on the perineum. In puerperal infection, where there are clots or pieces of placenta in utero, pituitary extract may also be useful. In the last sixteen cases which I have delivered, which required the use of forceps and in which I anticipated postpartum hemorrhage, I have given an ampule of pituitary extract immediately after the baby was born and ergot as soon as the placenta was out. Previously, my practice had been to clean out the placenta by hand and pack the uterus. That is a little bit risky for the general practitioner. I have thus found it possible to avoid the use of gauze. Of the sixteen cases I had to pack only one.

Dr. J. L. Bubis, Cleveland: During the last six years I have never given more than from 1 to 3 minims of pituitary extract during childbirth. With this dose given intramuscularly into the biceps in any stage of labor, my results have been most satisfactory. The 1 to 3 minim dose stimulates the uterine pains when very often a larger dose would be very dangerous to both mother and child. In postpartum hemorrhage there is no drug that will act so quickly. The danger of relaxation after severe contraction may be overcome by ergot. As a galactagogue pituitary extract has not been satisfactory.

In cases of retention of urine, it has been used with varying success. I have had better results from the introduction of one-half ounce of glycerin into the bladder. This has done away with probably 95 per cent. of catheterization in obstetric and surgical cases. In the removal of retained secundines I have used 1 c.c. of pituitary extract intramuscularly. By the time the uterus is cleaned out with the placental forceps, finger or curet, the pituitary extract has so contracted it that there is practically no bleeding and the uterus remains firm. Hot irrigations and packings are not necessary. At the end of the second stage of labor, pituitary extract is also effectual. We generally use gas anesthesia. Very often, just as the head reaches the perineum, the patient is placed under gas anesthesia and the labor pains cease. With the injection of 1 or 2 minims of pituitary extract the labor pains immediately recur.

Dr. Jennings C. Litzenberg, Minneapolis: In 1914 I sounded a warning against the promiscuous use of pituitary extract. My warnings were based on the observation of a relatively small number of cases, but it seemed to me that there was much danger of rupture of the uterus. Another indication, one which has not been mentioned by the essayist or in the discussion, is that of hemorrhage in the brain of the fetus, which we have seen in cases in which labor was entirely normal in every way except that pituitary extract was given at the end, when labor had nearly stopped, with the head on the perineum. The baby, alive at the time the pituitary extract was given, was born dead in a short time, and the postmortem showed hemorrhage of the brain. This paper is certainly timely for its warning against the promiscuous use of pituitary extract. I hope it will have the effect that no one will ever give an ampule of pituitary extract before the baby is born, but only very small doses before delivery; also, that it shall never be given, except in the most exceptional circumstances, before the cervix is fully dilated, and even after that with the greatest care and with ample preparations for complications.

Dr. C. S. Bacon, Chicago: One phase of this subject which has not been alluded to is the medicolegal question. I have seen a number of cases in which this phase of the problem was encountered. I know of one case in which a practitioner was blamed because he did not use pituitary extract in place of doing a forceps operation which resulted unfortunately. In a case in which pituitary extract is used and the baby born dead, or where there are serious lacerations of either the cervix or perineum or of the pelvic outlet, there is a greater legal risk. This feature should be considered carefully. The initial dose of pituitary extract should always be small. For some years I have not ventured to give more than from 3 to 5 minims of the extract as the beginning dose. When, however, a patient does not react to this dose, I do not hesitate to give more, but under exceedingly careful observation of the case.

Dr. W. P. Manton, Detroit: I have tried out pituitary extract in a limited number of cases and my findings agree practically with Dr. Kosmak's experience. The period of rehabilitation of which Dr. Litzenberg speaks is one of special importance for the general practitioner, and will probably never arrive.

AVOIDABLE TRAUMATIC ABDOMEN *

JOHN B. DEAVER, M.D.

PHILADELPHIA

At this time when so much unavoidable injury is occupying the attention of the surgical world, the surgeon in civilian practice is more than ever shocked on being confronted with traumatism that could be avoided. This was forcibly brought home to me recently while operating for symptoms of a severe abdominal lesion:

> A colored woman, aged 49, had been operated on twelve years previously (operator unknown) for a tumor of the uterus, abscess and appendicitis. After two months at the hospital, she had been dismissed in good condition and had remained perfectly well until her present illness, which had set in with severe abdominal pain six days prior to her coming to the hospital.
>
> I was not a little astounded to find the trouble to have been caused by a pair of hemostatic forceps 8 inches long, one half of which was found in the sigmoid and the other half in the lower ileum which it had perforated, producing a spontaneous ileosigmoidostomy. The instrument was removed and the bowel closed; it was corroded but not covered with a membrane. The entire lower abdomen, the site of a purulent peritonitis, was tied up with adhesions, some of which it was deemed best not to attempt to separate. The patient made an uneventful recovery and was discharged in good condition one month after operation.

The case appears unique, both for the length of time the foreign body had been within the abdominal cavity without causing any trouble and for the unaccountable manner in which the instrument had separated and found lodgment in different parts of the bowel.

CAUSES AND EFFECTS OF OPERATIVE OVERSIGHT

Numerous systems and devices have been suggested to avoid this accident, but they are usually more or less cumbersome and often fail of the very purpose for which they are designed. In the last analysis, the proper organization of the operating room is the vital factor in preventing this mishap. The essentials are absolute quiet, a permanent staff of well trained, reliable assistants, each assigned to a particular task, whose conscientious and concentrated attention to this task and unremitting persistence in tracing any piece of gauze or instrument that may be missing is second only to the vigilance of the operator himself. Those of us who are fortunate enough to have at our command such a staff are also fortunate enough not to have such an oversight on record.

---

* Read before the Section on Obstetrics, Gynecology and Abdominal Surgery at the Sixty-Ninth Annual Session of the American Medical Association, Chicago, June, 1918.

Some surgeons, who with commendable frankness have published their sins in leaving a foreign body within the abdomen during operation, have offered extenuating circumstances to explain the misfortune, such as unusually difficult and prolonged operation with threatened collapse of the patient and necessarily hurried termination of the operation in order to save life. The oversight would be possible in such circumstances, especially if the operator was young, but it is here where the training of his staff proves of inestimable worth.

The possible dire results of the occurrence are threefold: death, prolonged suffering and often abscess formation, usually with recovery, and not infrequently a lawsuit, which, no matter how it terminates, means an irretrievable loss of time and of reputation to the surgeon.

Fortunately, a beneficent provision of nature enables the peritoneal cavity to protect itself from the evil effects of a foreign body in its midst, and its presence is often one of the surprises of the postmortem table. In a great many instances, too, the forgotten object is passed spontaneously through the rectum and sometimes it is recovered through an abscess or a sinus. But more often it entails a secondary operation immediately after the primary one, or, as in our case, at some more or less remote period afterward. The outcome is not always so fortunate, for death as the result of the presence of the foreign body and its attendant complications is the result in more than one fourth of the reported cases.

PERFORATION OF THE UTERUS

This type of avoidable traumatism suggests another type which is perhaps less pardonable than the foregoing and which is attended with equally unpleasant possibilities. I refer to perforation of the uterus. The avoidance of this accident is entirely a matter of instruction and technic. The frequency with which it is still reported (and it is probably not reported as often as it occurs) would seem to indicate that curettement is still considered an easy and simple operation which every beginner may safely undertake. The fact of the matter is that it is a serious operation and that only the experienced surgeon is able to recognize when a false passage has been made and can at once proceed to correct it. The tyro in surgery usually does not know what he has done or realizes it only when to his horror he finds that what he is drawing out is not membrane but intestine. In other words, the expert immediately knows when he is encountering unusual conditions, such as soft uterine tissue, which offers no resistance to any instrument, or abnormal anatomic relations, such as retroflexion; and he acts accordingly. In the event of perforation, prompt action usually prevents any untoward result and recovery takes place. But should the accident happen to one who is not experienced, death is the more common result, due often to imperfect aseptic precautions and lack of training or lack of proper facilities to do an abdominal section to repair the injury.

One way of avoiding the accident is by careful preliminary estimation of the position, mobility, consistency, and, if possible, contractility of the uterus, and by noting the presence of obstruction, such as tumors, and the condition of the adnexa. Another way is to use nature's best curet, the fingers of the experienced surgeon. Should an instrument be required, it should be a dull one, preferably placental forceps. The dull curet may, but the sharp one does do harm. The former removes epithelium but the latter removes mucosa as well, which leads to a permanent loss of substance, for repair in such an event takes place by the formation of connective tissue and produces a focus of reduced resistance and a predisposition to rupture.

It is also well to remember that perforation of the uterus has resulted in some instances from the injection of caustic solutions, such as chlorid of iron or of zinc, tincture of iodin, etc. In the special cases in which such solutions are found necessary, they should be applied with a swab.

RUPTURE OF THE UTERUS

In the list of avoidable abdominal traumatisms, we must also include rupture of the uterus with its shockingly high maternal and fetal mortality. While it is possible that a percentage of the complete traumatic ruptures produced by operation have been preceded by a slight degree of spontaneous rupture of the uterus, there is sufficient evidence to show that by far the greater number of cases are actually traumatic, the direct result of inexperience and ignorance, of failure to recognize that rupture is threatening or at least to recognize that things are not as they should be, of faulty manipulation, hasty instrumentation, and, in not a few instances, of the administration of pituitary solution.

The only hope of improving the dark prognosis of this very serious condition is abdominal section at the first sign of spontaneous rupture. Any other procedure, such as drawing the fetus through the rupture and delivery in the natural way runs the risk of additional injury and of infection and is also contrary to the principles of good surgery which abhors work in the dark, but prefers the light by which it may see well what is to be done and do well what is to be done.

In a few exceptional cases, when the rupture is in the lower uterine segment, packing the uterus and the pelvic cavity with gauze has given good results, but when the rupture is anterior or lateral and when there is marked hemorrhage and the placenta or the fetus has escaped into the abdominal cavity, abdominal section is imperative and most likely a hysterectomy will be required. The safest course in all ruptures is operation.

The advantage of abdominal section is the opportunity it presents of complete cleansing of the operation area, control of hemorrhage, examination and proper treatment of the collapsed intestine, and the possibility of conservative treatment of the ruptured organ. Supravaginal amputation which is advocated by some surgeons, it is true, preserves the pelvic floor intact and permits menstruation, but it removes the sound and noninfected corpus and allows the lacerated cervix to remain. For this reason, total extirpation is better when the vaginal portion is torn and requires suture.

The best thing, however, is to do everything possible to avoid the accident by careful study of conditions—the comparative size of the fetus and the pelvis and the degree of expulsive power. The ability to recognize impending rupture, and prompt action to resist it are greatly needed.

USE OF NITROUS OXID GAS

A few words with regard to nitrous oxid gas and nitrous oxid and oxygen anesthesia in surgical and obstetric work may not be out of place in this connection.

While I have found this form of narcosis useful in short operations, especially appendectomy in chronic appendicitis, I should not be inclined to advocate it for more extensive and prolonged work. Its great disadvantage seems to me to be that it does not give complete anesthesia, and thus it prevents that perfect relaxation of the patient and at the same time that perfect control by the surgeon, who should be monarch of all he surveys. The amount of gas to be given is also difficult to determine even after extended practice in its administration, and the surgeon's attention is apt to have to be divided between the state of his patient and the work he is doing, at least more so than with ether anesthesia in the hands of a competent anesthetist.

Conservation, the watchword in civilian life today, has ever been the watchword of medicine. It behooves us at this time more than ever, by precept and by example, to leave nothing undone that will avoid unnecessary suffering and unnecessary risk to life, also unnecessary drain on our much depleted hospital and teaching staffs, to say nothing of the drain on the purse of the patients. It is for these reasons that I have chosen to sound this warning note at this time.

ABSTRACT OF DISCUSSION

Dr. Stephen E. Tracy, Philadelphia: Two or three years ago a patient came under my observation complaining of symptoms from a mass in the middle zone left side of the abdomen. The patient was studied carefully and finally a diagnosis of malignancy of the colon was made. At operation a block dissection was made; over half of the transverse and nearly all of the descending colon was removed. There was an opening between the mass and the lumen of the colon through which a piece of gauze protruded. The cavity when open revealed a considerable quantity of pus and a gauze pad. The patient had had a hysterectomy seventeen years before. She had had no symptoms from the gauze until about six months before she came under our observation.

Dr. Peter B. Salatich, New Orleans: Some time ago a man told me that he had resected 3 feet of bowel and the woman got well. It was learned that he had curetted the womb for abortion. He curetted and curetted and did not recognize the condition until the bowel was hanging out of the vagina. He had taken out 3 feet of bowel and boasted of what a wonderful operation he had performed.

Dr. Emil Novak, Baltimore: I saw a case of perforation of the genital tract which was rather striking in that severe injury to the intestine was caused by the patient herself. The patient was brought to the hospital, apparently moribund. A few days before, thinking she was pregnant, she had introduced a rough splinter of wood into the vagina, directing it upward in the general direction of the uterus. A few hours later she had a desire to defecate. During the straining she felt something come out between her limbs. She did not know what it was, but, nevertheless, she took a pair of scissors and cut it off. It proved to be a loop of her own intestine. Dr. Deaver has done a service to gynecology in emphasizing the dangers of curettage, usually considered a very simple operation. Nevertheless, the dangers of operation are not nearly so great as Dr. Deaver has painted them—certainly not great enough to justify the routine performance of transperitoneal hysterotomy. While the danger of perforation of the uterus is a real one, the accident should not be of very frequent occurrence if the operation is done with the proper care. As a rule, the uterus is perforated on the instroke of the curet. I have often seen men, in using a curet, grasp it as if it were a poker, thrusting it forcibly into the fundus. The instrument should be allowed to slide up toward the fundus practically by its own weight. The outward stroke can be made much more briskly, for there is little danger of perforating the uterus during this step of the procedure.

Dr. Deaver's allusion to the subject of rupture of the uterus interested me, especially because of a recent personal experience. In this case the rupture followed a previous cesarean section, and was noteworthy because of the absence of the shock and hemorrhage usually observed in uterine rupture. I saw the woman in consultation six weeks after the expected date of confinement. At the latter time she had had a spurious labor which had left her with a moderate amount of abdominal soreness. The woman had, however, been walking about the hospital and feeling fairly comfortable up to the time I saw her. In view of the absence of a presenting part or fetal heart sounds, rupture of the uterus, with extrusion of the fetus into the abdominal cavity, was diagnosed. At operation a large macerated fetus was removed from the abdominal cavity, the ruptured uterus having undergone involution and having again become a pelvic organ. Rupture of the uterus had apparently been attended with no hemorrhage, probably on account of the tamponlike action of the fetal head as it was extruded through the uterine wound.

Dr. A. E. Walker, Anthony, Kan.: I was called to curet a woman from whom a young physician had removed 40 inches of bowel. I opened the abdomen and found two perforations in the anterior wall. The uterus was retroflexed, making perforation quite easy.

Dr. A. P. Butt, Davis, W. Va.: I do not think the impression ought to be allowed to go out that these are all avoidable accidents. We are not all surrounded with the appointments which Dr. Deaver has in his operations, and these accidents are bound to occur. Those of us who attended Dr. Murphy's clinics remember how sponges were counted and foreign bodies explored for. He always did that, and I presume Dr. Murphy had some reason for so doing.

Dr. John B. Deaver, Philadelphia: I am much obliged to the gentlemen for discussing my paper. After years of experience in removing foreign bodies, this instance in which the forceps were found, after having separated and perforated the bowel, was unique.

Progress in China.—The usual missionary program, with its threefold emphasis on education, medicine and religious teaching, is in China the agent of reconstructing whole communities and of creating a new type of life. In hundreds of cities and villages today these effects are evident: an increase of general intelligence; a greater capacity on the part of young men and women to support themselves well, due to the training obtained in church and school; a decrease of prevalent diseases; cleaner and more beautiful homes; a new appreciation of the dignity of womanhood; a deeper interest on the part of the community in the welfare of the defectives and of the poor; the breaking down of fixed and hardened social customs and a greater ambition and zest to life on the part of young men and women; a new spirit of unity and cooperation in the Christian community; the breaking down of the bondage of demonology and a release of high spiritual hopes and aspirations. While all these effects are not evident in every community, they are the obvious effects of Christian missions in China.—J. S. Burgess, the *Survey*.

TREATMENT OF PREMATURITY*

ROOD TAYLOR, M.D., D.Sc.
ROCHESTER, MINN.

It is my purpose to present in this paper the method and the results of the treatment of premature infants in the University of Minnesota Hospital. The material studied includes sixty prematurely born infants, all being born at, or otherwise admitted to, the clinic from September, 1914, when the department of pediatrics assumed charge of the new-born infants' clinic, until the close of 1917.

It is noteworthy that Litzenberg's[1] report of the efficacy of the four-hour feeding interval for premature infants, the first report in American literature, came from the obstetric service of the same hospital. As Litzenberg states, he was led to adopt the long interval by observing its success in a premature baby that vomited whenever a shorter interval was tried. No less an authority than Czerny had previously recommended that the premature baby be given no more than six feedings in the twenty-four hours. Since Litzenberg's paper, another by Grulee[2] has appeared reporting success with, and advocating the use of, the four-hour feeding interval, stating that it tends to prevent overfeeding, to avoid vomiting, a serious complication, and to avoid disturbing the infant.

Our experience supports Grulee's summing up, and we see only one disadvantage of major importance inherent in the practice of four-hour feeding. This is that in certain homes where insufficient effort is made thoroughly to empty the breasts, they will be inadequately stimulated and the milk supply will suffer correspondingly.

The babies in this series were fed breast milk on the four-hour interval, with a few exceptions in the second month, no other food was used. Many of them were tube-fed for varying lengths of time, a procedure first employed by Tarnier,[3] and later advocated by Rott[4] and by Langstein.[5] The tube, a small, soft rubber catheter attached to a glass funnel, was passed by mouth and inserted about 15 cm. No injury to the babies ever resulted. The tube feeding was continued until the babies were able to nurse or take the bottle successfully. The smaller babies, weighing 2,000 gm. and less, accomplished this, on the average, at the end of the first month. Only one required two months before being able to take the breast. Two thirds of the infants with a birth weight of more than 2,000 gm. took the breast successfully in the first week. Only three needed to be tube-fed in the third week.

Table 1 shows the birth weights of the babies who survived and the day on which they began to take considerable nourishment directly from the breast. Nearly half these babies, however, required complemental feedings for a week or two longer, that is, they were weighed before and after nursing, and the deficiency was made up by tube or bottle. The breast supply of the mothers was kept up by manual expression or pumping, many of them sending their milk in twice a day by messenger.

Feeding, as a rule, was begun on the second day, the initial amounts being usually from 15 to 30 gm. six times in twenty-four hours. Oberwarth,[6] Birk[7] and Ladd[8] have found the daily caloric need of the premature infant to be slightly in excess of 100 calories per kilogram. Salge[9] and Budin[10] place the amount about 50 per cent. higher, while Czerny and Keller give figures that lie between the two. According to Birk, after the tenth day, the premature baby needs about one seventh of his body weight in breast milk daily. It would seem—and this was our experience—that no average applies to the individual baby. The chief factor to be considered is that the baby's tolerance for food must not be overstepped. Vomiting (other than an occasional slight regurgitation when the tube is withdrawn) seems to be the first danger signal, and on numerous occasions the baby's *ration* was temporarily reduced when this appeared. Certainly one should not wait for other evidences of overfeeding, such as diarrhea or irregular temperature.

TABLE 1.—BIRTH WEIGHT, CONTROL OF TEMPERATURE AND DATE OF FIRST SUCCESSFUL NURSING IN SURVIVING INFANTS

Case Number	Birth Weight, Gm.	Day on Which Temperature Was First Controlled	Day of First Successful Nursing

ADJUSTMENT OF TEMPERATURE

Incubators were not used. Instead, the babies, clad in flannel hoods and capes, were kept in blanket-lined clothes baskets containing hot water bottles. The bed temperatures were charted along with that of the baby, and held at between 85 and 90 F. Genersich[11] gives this as the optimal temperature for the premature infant's bed. None of our babies that were unable to

maintain a normal body temperature with a bed temperature of 90 were able to do so when the bed temperature was higher. Our charts show that when the baby can maintain a normal monothermia with the aid of hot water bottles, the temperature will remain between 98 and 99 F. without them.

The bed temperatures were taken and charted after artificial heat was discontinued, and in babies that were controlling their body temperatures the bed temperatures were uniformly between 85 and 90 F. The temperatures of the bed of another premature baby, whose own body temperature remained between 97 and 98 F., was constantly in the neighborhood of 80.

Fifteen of the babies who survived had birth weights of 2 kg. or less. On the average, they were able to control their body heat by the twenty-seventh day. Only three required hot water bottles longer than a month. One, however, needed artificial heat until he was 72 days old. None of the premature babies with a birth weight of more than 2,000 gm. required artificial heat after the first month. Twenty-one of these survived and only three needed it in the fourth week. Table 1 shows the day on which the infants began to maintain their body temperature without artificial heat.

The babies were bathed with olive oil and wiped dry with warm flannel. An aseptic nursing technic was followed, nurses and doctors washing their hands before and after contact with the infants, and wearing gauze masks if suffering with any respiratory infection, however mild. The mothers of premature infants were carefully watched, and at the first sign of coryza were made to wear masks while nursing their babies.

STATISTICS OF MORTALITY FOR SURVIVORS AND NONSURVIVORS

Of the sixty premature infants, thirty-six lived and twenty-four died, giving a gross mortality of 40 per cent. Fourteen deaths, however, or 58 per cent. of the total number of deaths, occurred on the first day. Necropsies were done on twelve of the fourteen babies, and in five instances definite and adequate causes for death were found. There was extensive visceral syphilis in two cases, anencephalus in one, intraventricular hemorrhage in one, and a fractured dorsal vertebra with a lacerated spinal cord in one. Two died on the second day, one on the third, one on the fifth, and one on the sixth, all with cyanosis and a gradual decline in body temperature. One infant survived until the eighth day and another until the thirteenth day, both showing throughout a slowly falling temperature. Necropsies were done in five of the seven cases without a satisfactory cause of death being found. Of the remaining thirty-nine babies, one with syphilis died on the twenty-fifth day of hemorrhage from the stomach, and one died on the forty-second day because his tolerance for breast milk had been overstepped. This baby apparently had taken his food well and was making a satisfactory gain in weight; but the food was increased too rapidly, the warning signal of vomiting was disregarded, diarrhea and eczema developed, and thereafter a quantity of nourishment great enough to maintain life could not be tolerated. The only other death occurred on the fifty-first day in a baby that contracted rhinitis from some careless attendant; the temperature became irregular, the tolerance for food was lost and death ensued. The last two babies were born of mothers each of whom had an open pulmonary tuberculosis. No tuberculosis was found at the necropsies of the infants, but, as Reiche[12] has pointed out, maternal tuberculosis exerts a harmful influence on the premature infant, even when the latter does not suffer from the disease.

TABLE 2.—RECORDS OF PREMATURE INFANTS SURVIVING SIX DAYS

Case Number	Birth Weight, Gm.	Day of Death	Probable Cause of Failure	Pathology
11134	975	8	Gradual decline in body temperature	No necropsy

11490	2,200	2	No necropsy
958	2,220	2	Necropsy negative

Budin pointed out the great importance of initial chilling in producing the death of the premature infant. This most frequently occurs when the baby is born outside the hospital. Consequently, while our mortality rate is much increased by the fourteen infants who were born there and died on the first day, it suffered very little from the deaths of infants who were brought in from outside to die later. Only one such death occurred.

Table 2 shows the birth weight, the age at death and its cause in the six infants who survived longer than five days. Similar data concerning the eighteen infants who died in the first five days is contained in Table 3. It is a question as to how many of these babies were viable.

PROGRESS OF SURVIVING INFANTS

A summary of the more important information gleaned from the records of the surviving babies is presented in Table 4. It shows the progress of each baby, the ability to control temperature, to nurse, and to gain in weight. The age figures are given in days, the weights in grams. The + signs in the tenth column signify that complemental feeding was still necessary at the time of discharge, those in the eleventh, that the baby was nursing well at discharge, and those in the twelfth that at that time he was gaining satisfactorily.

The parallelism between the ability fully to control body temperature and to gain satisfactorily in weight is noted. Six of the nine babies that were discharged before they were able to maintain a normal monothermia were not yet making a good gain. Because of the advantage of keeping the baby with its mother, all infants were discharged as soon as it seemed safe to discharge them. All but two babies, however, were either nursing well or gaining satisfactorily at the time of leaving the hospital. Only three infants remained in the hospital longer than two months, and two of these developed marked pallor and craniotabes in the third month. As has been pointed out by Rosenstern[13] and others, the so-called pseudorickets uniformly occurs at this period of premature life. These babies were given iron and cod liver oil and showed improvement. It would seem advisable, if not contraindicated, to start such medication as early as the second month.

[12] Reiche, A.: Das Wachstum der Frühgeburten in den ersten Lebensmonaten, Ztschr. f. Kinderh., 1915, 12, 369-401.

CONCLUSION

It is found that of sixty infants fed breast milk on the four-hour interval, by tube when necessary, kept sufficiently warm and protected against infection, thirty-six lived and twenty-four died, a gross mortality of 40 per cent. When, however, one deducts the fourteen deaths occurring on the first day, the mortality rate of the remaining forty-six cases falls to 22 per cent.

The most favorable view of the treatment employed is gained if only the forty-two babies living longer than five days are considered. Among these, including two who by better judgment and technic could have been saved, there were six deaths, giving a mortality of 14 per cent.[14]

ABSTRACT OF DISCUSSION

Dr. John Zahorsky, St. Louis: I have been much interested in the question of the premature infant for several years. It is much better practice to decide daily how much milk the baby shall have, by any method you choose. Write on the directions just the quantity of milk the baby should have each day, and the nurse should be instructed to give that amount *in twenty-four hours. In other words, prescribe daily rations,* and then try to get it to the baby. Sometimes you can do it on a four-hour schedule, and sometimes you have to feed more often to get the proper quantity. The feeding is the most important part of the care of the premature infant, not the regulation of the temperature. I always try to work on an energy quotient of 120 to 130 by the tenth day. I commence usually with only one fourth of that quantity—one fourth of 120, or an energy quotient of about 30 the first day, and gradually increase from day to day, until we have worked up to 120 or 130. This varies with the baby. I do not believe the interval makes any material difference. What does matter is that you get into the baby the required quantity of food. The *symptom of cyanosis which comes frequently* is due to apnea, and may frequently be due to exhaustion. There is not enough energy to keep up respiratory efforts. It is necessary to get *sufficient food into the baby, regardless of the intervals* between feedings.

As to the question of temperature, I think it is a little high in this paper. With a small baby, under 2,000 gm., it is necessary to commence with a temperature of from 85 to 90; you want to gradually reduce this temperature, because slightly overheating a baby often produces cyanosis, and not only that, it seems to diminish the internal power of oxidation. I like to keep the baby as cool *as possible, and still* maintain a bodily temperature of at least 98 degrees. The most important symptom to combat with a premature baby is apnea. Cyanosis is liable to occur *in* any feeble infant. To prevent this, in the first place I think a proper fat supply should be maintained. It might occur, of course, from overfeeding or from infection. These cases are always given some respiratory stimulant, in addition to oxygen to dispel the cyanosis, usually caffein or small quantities of tea. I think caffein is very helpful in stimulating the respiratory centers.

[14] In addition to the references already given, the following will be found of interest:

La Fetra, L. E.: The Hospital Care of Premature Infants, Arch. Pediat., 1916, **33**, 352-356.

Dr. Isaac A. Abt, Chicago: I presume four-hour feedings will work out in a certain number of cases, even with premature babies. It seems to me that if a premature baby is fed only once in four hours, it will have to take a larger quantity at each feeding than if it were nursed every two or three hours. A baby's stomach at this time is naturally limited in size, and it appears to me that one gets better results if the baby is fed small quantities at relatively frequent intervals. I do not believe that the four-hour feeding plan should become a dogma. I see men who believe it is their whole business to have a baby fed only once in four hours, and if they think you order feedings every three hours they stand aghast. After all, we are dealing with individuals, and while a certain number of prematures may do well on four-hour feedings, I believe most prematures should be fed more frequently—possibly every two or three hours. Budin laid down the principles in his little book that prematures suffer from two great troubles—one, difficulty in maintaining body temperature, and secondly, most of them fail to prosper because of insufficient food. It seems to me, in order to supply the amount of food they need, they should be fed small quantities at frequent intervals. Dr. Taylor has already made the point that these babies should receive breast milk. This should be emphasized over and over again. Premature babies who are fed malted milk or condensed milk, or even cow's milk diluted, are extremely difficult to raise. I believe no real success can be obtained with these infants unless they receive breast milk.

Dr. Lawrence T. Royster, Norfolk, Va.: Most of the work I have done with prematures has been in private practice, outside of hospitals—a number were in outlying country districts where facilities were few and nurses often not available. I have met with some degree of success. As Dr. Abt has said, we must consider the individuality of the patient. The stomach of the premature infant varies just as much as the full-term infant's stomach does. Therefore, the ratio between the quantity given and the size of the stomach must be studied individually. I do not believe I ever fed a premature infant at four-hour intervals. From the standpoint of a private practitioner, outside of hospitals, I do not believe that it is feasible without a stomach tube. I do not use a stomach tube frequently because I have not often a person near who is qualified to do it. Of course, where there is no nursing power, that is essential. My most frequent interval for the first few days is two hours, and 1 to 2 drams is all that we can get in. I have tried a larger amount and a longer interval, but found that the babies did not thrive. Breast milk in these cases is almost a sine qua non. Some of the smallest premature babies I have ever reared never had a drop of breast milk. My plan in these cases has been to start with whey. Some will criticize this. However, I am talking from experience. Whey, diluted or whole, according to the patients' ability to assimilate, is a very good substitute for tiding over this time. After they take this, I then go to a straight modification of cow's milk.

Prematurity, of course, is a terrible handicap for a baby. A great many premature babies come as a result of various "accouchement forcé" methods which may be necessary on account of the condition of the mother. I do not wish to enter into a discussion of cesarean section, etc., but we have found that premature babies who have come as a result of cesarean section have given us an easier task than those brought into the world by rapid dilatation, and then the necessitated handling of the child with forceps.

Dr. Frank C. Neff, Kansas City, Mo.: I think we should not overlook one thing Dr. Taylor has mentioned, and that is the aseptic handling of these babies. As you all know, premature babies are a matter of great curiosity. I have found it very difficult to keep visitors away, and it can easily be seen how infection can occur. As to what Dr. Royster said as to feeding these babies with a tube, I do not think it is particularly difficult. On several occasions I have shown the mother how to use the tube, and she has done it successfully. I want to ask Dr. Taylor one thing: At what period does a gain in weight usually begin?

Dr. Jane M. Ketcham, Indianapolis: Premature babies should not be overhandled. With them I use a stomach tube every four hours for the first week. In the effort to get the child to nurse it is often handled too long and becomes chilled, and thus you defeat your own end. The stomach tube is a great advantage. After the child has the strength to nurse it is better for it to make the effort. It is an advantage to have the baby weighed before and after every feeding, so that we may know how much it is receiving. The symptom of vomiting is of the greatest importance and must not be overlooked, because when a child once begins to vomit it is impossible to know how much food it is retaining or for it to retain sufficient. The symptom of cyanosis can best be treated by oxygen, hypodermically, or by 5 to 20 per cent. glucose solution. The body fluids must be kept up at all costs. This is equally as important as maintaining an equable temperature. Great care must be taken not to overhandle a child.

Dr. Jules M. Brady, St. Louis: When this four-hour interval was first called to my attention in 1910, I did not see how it was possible to get sufficient nourishment into a premature infant in this way. It is like everything else—we have to try it to be convinced. Having had experience in numerous hospital cases, I have been convinced. There is one symptom that will throw a scare into one, and that is vomiting. When this appears, I think the chances of bringing through the premature are diminished. Feeding breast milk at four-hour intervals I think is the best method to prevent the appearance of this vomiting, which is so dangerous to the premature infant. If you cannot get breast milk, as sometimes occurs, I believe it is necessary to feed at shorter intervals.

Dr. Jay I. Durand, Seattle: Hunger is a detriment to a baby, and keeping babies on a starvation diet has, I think, done more damage than any other one fault in our infant feeding. Barley water for more than a twenty-four-hour period is never necessary in gastro-intestinal disturbances, and no variation of the normal feeding need be made in parenteral disturbances except the reduction, which no child voluntarily makes by refusing part of the nursing. The younger the baby, the greater is the danger from hunger. In prematures, the four-hour interval is the best. I had one premature of 2 pounds 3 ounces, which gained beautifully on four-hour feeding intervals, but you must see to it that the infant gets enough to cover its caloric needs. If the baby does not take enough from the breast, bottle, dropper or Breck's feeder, gavage must be used.

Dr. Edgar J. Huenekens, Minneapolis: I am especially interested in the rickets or pseudorickets that these premature infants develop. In a recent series of cases, I found 92 per cent. showed evidences of rickets. I believe this depends on a shortage of calcium in the infant's organism. Basing my treatment on the work Schloss has done in the treatment of rickets in breast-fed infants, I give these babies tricalcium phosphate with cod liver oil. I use a 10 per cent. mixture of tricalcium phosphate in an emulsion of cod liver oil. The results seem to warrant further trial.

Dr. Harry Lowenburg, Philadelphia: Several years ago in discussing this subject, I took the stand that we should treat the individual. It is very dangerous to become dogmatic about anything in medicine, especially infant feeding. Another thing comes to my mind, and that is that in passing the tube to feed these infants, it is much easier in my experience to pass it through the nose. I have also used a 5 per cent. sterile solution of glucose injected through the anterior fontanel directly into the longitudinal sinus, and I feel that it has done some good. Obstetricians are the chief offenders in destroying the maternal milk supply. I think that they should be told that either they should learn the principles of infant feeding, or leave the premature infant alone, as well as other infants.

Dr. F. C. Wahrer, Fort Madison, Iowa: Prematurity is the exception, and when we are making rules, let us not forget the exceptions. When you make a rule for all, you must use the rule and the exception; in some cases the rule may apply, in some the exception—and in some others the exception to the exception. Suppose a child is born four weeks too soon. At the end of two months is it 4 weeks old or 2 months? Does it still partake of the condition in utero pertaining before its birth? If it does, then there is some good sense in feeding a child at four-hour intervals, which would not have been fed anything if it had remained those four extra weeks in utero. I think it is a question whether it even needs to be fed as often as Dr. Taylor suggests. But since we cannot make rules for every child, we must adopt separate rules for each child, as I am sure that some premature children must be fed oftener than other equally premature children.

Dr. Abraham Jacobi, New York: I believe, as has been said, that every case has to be treated individually. You have to use your brains. I believe every one who has spoken was correct—correct in his own case—but only in his own case. We should study the babies and study the babies' mothers, and we will be better off. I am not in a position to say that your babies and the other doctors' babies will do well on the same treatment. That is impossible.

Dr. Rood Taylor, Rochester, Minn.: I went over the charts of Dr. Sedgwick's patients at the University of Minnesota Hospital. I was so much interested in what I found on those charts that I secured Dr. Sedgwick's permission to report what I found. All those babies happened to be fed on the four-hour interval. All the prematures did well on it. There is this to be said for using a standard interval—it helps one to gage when the tolerance of that particular baby is being overtaxed. Dr. Zahorsky mentioned the importance or nonimportance of the baby's maintaining its own temperature. There were nine patients in this series who were not maintaining temperatures very well. Of these, six were not gaining. As regards the small amounts of breast milk taken at a time, I think the reason most often is not the size of the baby's stomach, but the inability of the premature baby to nurse well, whether it is due to lack of the sucking reflex or what not. The stomach of the new-born is much more active than that of the adult, and the stomach of the premature infant is much more active than that of the new-born, as the latter is more active than the stomach of the adult. Although no work has been done on the subject, I believe the stomach of the premature infant empties itself more rapidly than the stomach of the full-term infant.

We do not see in the hospital, nor have I seen outside of it, women with premature babies, who did not have breast milk. Some of these women were very sick, and some septic, but if we wait long enough there will be breast milk. Without exception, we have always had breast milk for the premature baby—that is, provided the mother lived. In regard to the use of the nasal tube, I have had no difficulty in passing the tube through the mouth, and I believe it is generally considered safer to pass through the mouth because of the danger of passing it in to the cranium. These babies gained weight very slowly, but came along all right in the end.

Health and Ethics.—The basis of ethics, then, is the health of the community. That fact we know, but we do not know it fully; we have not exhausted its riches. We have improved sanitation; we have improved the conditions of labor both as regards positive risks and the character of buildings. In these things the best and the most efficient have proved identical; so far economics has supported ethics. But economic production and efficiency are liable to be dangerous allies; we must not be led astray by a false ideal of industrial growth. Nor must we suppose that our duty ends with the physical welfare of the population. Already there are ample proofs that we shall be carried from external to internal conditions, from individual to racial questions, from health of body to health of mind. And by health of mind must be understood much more than crude questions of insanity, crime and feeblemindedness. The human race tends to emphasize more and more its own peculiar feature; its consciousness becomes more acute and more comprehensive; it cannot, like the animal, merely eat and drink and sleep; while we teach prudence and thrift we are developing, if I may so put it, the organs of worry and anxiety. This too will have its pathology, personal and social, an evil which is far from imaginary and has its witness in much of the present unrest. All these things must be included in our idea of the "public health" and we must organize for nothing less comprehensive.—G. S. Brett, *Public Health Journal*, August, 1918.

A FURTHER CONSIDERATION OF COMPLEMENT FIXATION IN TUBERCULOSIS *

V. H. MOON, M.Sc., M.D.
INDIANAPOLIS

The demonstration of antibodies in the circulating blood by complement fixation was first accomplished by Bordet and Gengou[1] and its application was made to tuberculosis by them several years before Wassermann and Bruck successfully applied the test in syphilis. If medical men should desire a less cumbersome term than the complement fixation test for tuberculosis it seems they could not do better than to term it simply "the Bordet test." The term has the advantage of brevity. It is historically accurate, and would fittingly perpetuate the name of the distinguished French investigator who first demonstrated the part played by complement in immune reactions—a discovery by which his German contemporaries were not slow to profit.

Wassermann and Bruck[2] made experiments with complement fixation in tuberculosis before they developed the test for syphilis, and subsequently Citron[3] made similar experiments. In these earlier tests, Koch's "old tuberculin" was used as antigen. For several years no marked progress was made in applying the test to the diagnosis of tuberculosis, possibly because of variation in the results in the earlier tests. Within recent years numerous articles have appeared reporting favorable results in the application of the test to extensive series of cases. The most significant feature of these reports is that, while there are differences in data and percentages due evidently to the different methods and reagents used, there is agreement that complement fixation under proper conditions gives positive results in the majority of cases of active tuberculosis. The laboratory technic employed in this test is the same in principle and in main details as in complement fixation applied to the diagnosis of syphilis. As in that test there have been many variations in the technic and in the reagents employed, and as would be expected, the results have also varied. The widest variation occurs in the preparation used as antigen, but each of the antigens used successfully has consisted of some preparation of tubercle bacilli. The reaction is one of biologic specificity depending on the presence in the patient's serum of free antibodies specific to tubercle bacilli. In this particular, the situation differs from that in syphilitic infection.

In reviewing the reports of this test, Miller[4] has classified the antigens into the following groups:

Group I. Antigens consisting of suspensions of whole or ground up tubercle bacilli.

Group II. Antigens which may be classed as tuberculins.

Group III. Antigens consisting of extracts or derivatives of tubercle bacilli.

Group IV. Preparations or extracts of normal and tuberculous organs, as lungs, lymph nodes, spleen, etc.

---

* From the Department of Pathology, Indiana University School of Medicine.

* Read before the Section on Pathology and Physiology at the Sixty-Ninth Annual Session of the American Medical Association, Chicago, June, 1918

[1] Bordet and Gengou: Compt. rend. Acad. de sc., 1903, **137**, 350. Ztschr. f. Immunitätsforsch. u. exper. Therap., 1914, **21**, 77.

Such antigens are analogous to the *original antigen* used by Wassermann in the complement fixation test for syphilis. Their use in tests for tuberculosis has not been attended with success sufficient to warrant serious consideration.

TESTS OF GROUP I ANTIGENS

Among the reported series of tests in which antigens of Group I were employed the following are cited as examples:

Caulfield and Beatty,[5] using "bacillen emulsion" as antigen, reported positive results in different types of tuberculosis ranging from 33 to 70 per cent. of cases. They also used Koch's old tuberculin as antigen in this same series of cases with positive results in less than 50 per cent. of the cases.

McIntosh and Fields,[6] after experimenting with various antigens, concluded that a suspension of living virulent tubercle bacilli constituted the best antigen. They reported positive results in pulmonary tuberculosis in 76.6 per cent. of the cases; in "surgical tuberculosis," 80.7 per cent., while among eighty-seven control cases only three were positive. It is of interest to note that two of these three cases were lepers, while the third was Addison's disease, which should be considered as tuberculous.

Radcliffe,[7] using a suspension of fresh tubercle bacilli as antigen, obtained 88.6 per cent. positive in early tuberculosis, 89.6 per cent. positive in moderately advanced tuberculosis, and 79 per cent. positive in far advanced cases. In 204 control cases there were no positives.

Miller and Zinsser[8] reported a remarkable series of tests, using as antigen tubercle bacilli from a large number of strains ground for an hour with dry salt and then suspended in distilled water. This antigen has the advantage of great simplicity in its preparation, and they stated that it will not deteriorate if kept for weeks at icebox temperature. They reported 284 cases of pulmonary tuberculosis with positive test in 97 per cent., 140 doubtful and suspicious cases with 22.8 per cent. positive, 113 inactive or arrested cases with 9 per cent. positive, while 144 nontuberculous controls were uniformly negative. Of forty-five Wassermann positive serums, only two were positive with their antigen. The writers stated that tuberculosis could not be positively excluded in these two cases.

Burns[9] and his colleagues, using Miller's antigen described in the foregoing, obtained equally consistent results, though their percentage was slightly lower than that of Miller and Zinsser. They compared the results of the tests with the patient's clinical condition, whether gaining or losing ground. They noted that patients who are holding their own, or gaining in physical condition, give the highest percentage of strongly positive tests, while those who are losing ground give the highest percentage of weakly positive or negative reactions. They regard the presence of complement-fixing substance in the blood as evidence of the patient's resistance and ability to form antibodies, and interpret the foregoing observations as revealing the amount of resistance the patient has available with which to combat the infection. Their view seems logical. We can readily understand how, when the system is being overwhelmed by the infection, the antibodies may be combined with the bacilli and their products as rapidly as the patient's system can elaborate them, thus leaving no free antibodies to be demonstrated by complement fixation. Conversely, if the patient is holding his own or gaining in condition, it is not surprising to find strongly positive reactions if the degree of the reaction is in any way dependent on the amount of free antibody in the circulating blood.

TESTS OF GROUP II ANTIGENS

Following are a few examples of reported series of tests using as antigen preparations of tubercle bacilli which may be classed as tuberculins, or Group II antigens.

Besredka[10] used a heated filtrate of tubercle bacilli which had been grown on a special culture medium. He found reactions uniformly positive in incipient and early tuberculosis, almost always positive in moderately advanced tuberculosis, and weakly positive or negative in far advanced cases. He laid stress on this point, since it made the test valuable in two ways: The fact that the test was uniformly strongly positive in early cases made it of especial value in the diagnosis of early and suspicious cases, while in well advanced cases in which the clinical evidence left no doubt as to the diagnosis, a weakly positive or negative test enabled him to offer a prognosis, since it served as an index to the patient's resistance. He observed, however, that the serum of syphilitic patients frequently gave a positive reaction with his antigen.

Inman,[11] using Besredka's antigen, obtained a positive reaction in ninety-five out of 100 cases of pulmonary tuberculosis. Of suspected cases in which there was no definite clinical evidence of tuberculosis, thirty out of fifty cases, or 60 per cent., were positive. Of 100 patients who were in the hospital for other conditions and in whom there was no suspicion of tuberculosis, twenty-four gave a positive test. Inman concluded that a positive test should be considered as evidence of an active tuberculous focus, while a negative reaction indicates either a healed lesion or absence of tuberculous infection.

Debains and Jupille,[12] using Besredka's antigen, obtained positive results in 90.5 per cent. of cases in the first and second stages and 81.3 per cent. in the second and third states of tuberculosis. Patients ill of other conditions than tuberculosis showed positive reactions in 17.3 per cent., while normal healthy persons were positive in 3.2 per cent. of the cases. The writers found that Wassermann positive serums gave positive results with Besredka's antigen in 24 per cent. of the cases.

Bronfenbrenner[13] used Besredka's antigen and conducted an elaborate study of various phases of the Bordet test. He also experimented with antigens prepared by the methods of Craig, Corper and Calmette. His investigations are of such significance that it is difficult adequately to review them in the limited space of this summary. Those who are interested are referred to his reports for particulars. He found positive results in 72 per cent. of clinically suspicious cases. Clinically tuberculous cases in the first stage were positive in 84 per cent., in the second stage in 94 per cent., while far advanced or third stage cases gave the remarkably low proportion of 15.3 per cent. positive. He found that a high percentage of Wassermann positive serums gave a positive reaction with Besredka's antigen, while 352 nonsyphilitic, nontuberculous controls were positive in 5.6 per cent. of the cases. He found that there is a "strain specificity" in the complement-fixing substance in serums from tuberculous patients, as evidenced by the fact that a given serum will give a positive reaction with antigen prepared from certain strains of tubercle bacilli, and weakly positive or negative reactions with antigens prepared from other strains. This probably accounts for many of the variations in the results of different investigators. It also gives point to the use of an antigen prepared from many strains of bacilli, that is, a polyvalent antigen. As to the fact that a high percentage of syphilitic serums give positive reactions, it is well known that the complement binding substance in syphilitic serum is not an antibody specific to the *Spirochaeta*, but is a lipotropic substance which may bind complement in the presence of the lipoidal substance present in tubercle bacilli, thus giving rise to false positives by cross fixation. Bronfenbrenner showed that the antibody in a tuberculous patient's serum is a specific antibody and that it is not lipotropic in character. This antibody reacts with the protein fraction of the antigen after the lipoidal fraction has been removed. He further showed that the serum of patients having both tuberculosis and syphilis contains both types of antibody, either of which could be exhausted from the serum by allowing it to combine with its appropriate antigen, leaving the other antibody present in the serum in undiminished quantity. On this basis he used Besredka's antigen freed by precipitation from its lipoidal substances, in an attempt to eliminate the false positives by cross fixation in syphilitic serum. His statement of the success of this is not clear. As to the remarkably low percentage of positive tests in far advanced tuberculosis, he stated it may be because (1) the resistance of the patient is exhausted, no new antibody being formed, and (2) the antibody is taken up by combination with the bacilli and their products in the system as rapidly as formed. This view, it will be noted, is in accord with that discussed earlier in this paper. Bronfenbrenner was able to verify this view by animal experimentation. He found that guinea-pigs inoculated with tubercle bacilli frequently gave positive complement fixation test as early as from five to seven days following the inoculation, while in advanced stages, from four to six weeks after inoculation, the test became negative. Bronfenbrenner concluded that positive fixation indicates active tuberculosis and that the application of complement fixation to the diagnosis of early tuberculosis is at hand.

Med., December, 1914, p. 786; Science, 1914, **39**, 808; Tr. Nat. Assn. for Study and Prevent. of Tuberc., 1916, **12**, 225; Proc. Soc. Exper. Biol. and Med., 1914, **11**, 92; Jour. Lab. and Clin. Med., 1917, **3**, 50.

Craig[14] used Besredka's antigen modified by extracting with alcohol. The antigen contained many strains of tubercle bacilli including the bovine type. His results were summarized in three groups.

1. This group consisted of 209 cases of known tuberculosis. The percentages were: incipient cases, 96.7 per cent. positive; moderately advanced cases, 98.3 per cent. positive, and far advanced cases, 96.3 per cent. positive, while inactive and arrested cases showed a much lower percentage.

2. The second group consisted of other clinical conditions. Four hundred and fifty patients, ill of other conditions, including syphilis, gave a positive test in 4.4 per cent. of the cases. Three hundred and fifty cases of syphilis were positive in 5.4 per cent. of the cases. Four of these cases were later diagnosed as tuberculosis by the finding of tubercle bacilli in the sputum.

3. The third group consisted of 200 healthy young soldiers. One case, or 0.5 per cent., gave a positive test and this soldier afterward developed active clinical tuberculosis.

Craig stated that this test will not give positive results in other conditions than tuberculosis, and that his results, together with others, demonstrate that complement fixation in tuberculosis has reached the stage at which it may be used with confidence by practitioners in the diagnosis and as a criterion of cure in tuberculosis. He also stated that a positive test means the presence of an active tuberculous focus, and that as long as the test remains positive the patient cannot be considered cured. He called attention to the fact that his series shows a higher percentage of positive reactions than he himself could obtain in a like series of Wassermann tests in cases of active syphilis. He believes it is only a matter of time until this test will be as widely used as the Wassermann test.

McCaskey[15] used Craig's antigen, but his percentages were much lower. Among thirty-six cases of clinical tuberculosis, twenty-eight cases, or 77.7 per cent., were positive. Among seventy-four cases of other diseases, fifteen cases, or 20.2 per cent., were positive. Among twenty-five cases with positive Wassermann tests, eleven cases, or 44 per cent., were positive. Only two of these had clinical evidence of tuberculosis.

Petroff,[16] using three different antigens, obtained highest results with one of his own modification, which may be classed in the group of tuberculin antigens. He obtained in suspicious or doubtful cases 65 per cent. of positives; in incipient cases 81.2 per cent. were positive; in moderately advanced cases 91 per cent. were positive. Far advanced cases were 100 per cent. positive, although his number of cases in this group was too small to be conclusive. In fourteen normal controls and seven cases of arrested tuberculosis the test was uniformly negative.

TEST OF GROUP III ANTIGENS

Following are a few examples of Group III antigens consisting of extracts or derivatives of tubercle bacilli.

Calmette and Massol[17] used a special water and peptone soluble preparation of bacilli with which they obtained positive results in 124 out of 134 known tuberculous cases, or 92.5 per cent.

Corper[18] used an antigen in which tubercle bacilli were autolyzed for days at incubation temperature in salt solution. His percentage of positive results was not so high as that of others, possibly because of the fact that his antigen was prepared from a single strain of tubercle bacilli, while the prevailing opinion is that a number of strains should be represented in the antigen. This point is especially emphasized by the work of Bronfenbrenner, Craig and Miller. Corper reported a considerable percentage of false positives resulting from cross fixation with syphilitic serum, and concluded that this occurred with sufficient frequency that a Wassermann test should be performed on all serums tested for tuberculosis, and in the presence of a positive Wassermann test a positive result with tuberculous antigen must be regarded as inconclusive.

Dudgeon, Meek and Wier,[19] after experimenting with a number of antigens, published their highest percentage of positive results from an alcoholic extract of tubercle bacilli. This gave 89.3 per cent. positives out of 234 cases of known tuberculosis.

If space permitted, many other equally valuable reports might be reviewed. I will close this section of the discussion by quoting one opinion from the clinical viewpoint. Dr. Meyer,[20] under whose clinical supervision this test was used diagnostically in hospitals for tuberculosis in New York, stated that the test was positive in 96 per cent. of tuberculous cases under his supervision, and that those cases in which it was negative were clinically arrested cases. He concluded as follows: "It is no exaggeration to say that the method equals in value the Wassermann test for syphilis. It is most important that complement fixation tests be made on as large a scale as possible both in sanatoriums and private life."

COMPARISON OF ANTIGENS

The foregoing reports, summarized in the accompanying tabulation, agree in the main particulars. Antigens prepared by widely different methods have given high percentage of positive tests especially in early tuberculosis, while the percentage of positives in normal individuals approaches zero. There is agreement that the test is most useful in detecting early cases, but there is difference in the evidence regarding far advanced cases, Bronfenbrenner and others finding a decrease in the percentages of positives in this group, while Miller, Craig and others find no such decrease. There is also a difference in the data regarding tests on syphilitic serum. This difference seems unexplainable when several investigators have used antigen prepared by the same method.

As to the antigens, it is difficult to draw conclusions as to their relative merits. Antigens from Groups I and II, however, seem to have produced the highest percentage of satisfactory tests. It seems to be agreed that the antigen should contain many strains of tubercle bacilli.

ANTIGEN PREPARED BY MILLER'S METHOD

My own experiments with this test began with experiments with antigen prepared by Miller's method. In the beginning, serums were used from known tuberculous cases only, and variations in technic were employed to establish a satisfactory working technic. It was soon found that specific antibody in tuberculous serum is often present in very small amount and that extreme care is necessary in the technic in testing for it. The sheep hemolytic system was used and the reagents were adjusted as follows before each test: Fresh sheep corpuscles, after repeated washing with salt solution, were centrifuged at a fixed speed for a fixed time, fifteen minutes. This was to secure a uniform packing of the corpuscles in order that quantitative measurement of them would be more accurate. A 2 per cent. suspension of these packed corpuscles was then made and the amount of fresh guinea-pig serum was determined which would cause complete hemolysis in thirty minutes at 38 C. of 0.5 c.c. of the 2 per cent. corpuscle suspension in the presence of two carefully determined units of hemolytic amboceptor. The total volume in all titrations and tests was brought to 1 c.c. by the addition of physiologic sodium chlorid solution.

* Various stages grouped.

In the making of the tests, two units of complement, determined as described, were incubated with 0.1 c.c. of the patient's serum and a suitable quantity of antigen for one hour, after which two units of amboceptor and 0.5 c.c. of 2 per cent. corpuscle suspension were added and again incubated for one hour. Suitable controls were made on each reagent used, and the antigen was never used in greater quantity than one third of the smallest amount that would give evidence of slight anticomplementary action. The objection is raised against using the sheep hemolytic system that it is necessary to inactivate the patient's serum by heating, and that this lessens considerably the activity of its antibodies. We found by trial that a temperature of 55 C. for five minutes is sufficient to destroy complement, so inactivation of the serums to be tested was done by heating to 55 C. for ten minutes. The shortened time of heating probably has less effect on the antibody content of the serum than the thirty minute period usually employed. It was found that 1 c.c. of the patient's serum was sufficient for the tests, as no positive tests were obtained by using a larger quantity of serum which was negative in 0.1 c.c. quantity.

The antigen employed was prepared by taking an equal quantity by weight of fresh tubercle bacilli from each of twelve different strains of the human type and four strains of the bovine type. This was mixed with sodium chlorid, C. P., according to Miller's formula: 20 mg. of bacilli plus 90 mg. salt, ground for an hour with a glass rod, then suspended in 10 c.c. of distilled water. The antigenic and anticomplementary quantities were determined by suitable titration. We allowed this suspension to autolyze for several days at 38 C., as suggested by Corper, with improvement in the quality of the antigen in some cases. However, unless strict asepsis was maintained in the preparation of the antigen the autolyzing process allowed contaminating organisms to develop causing undesirable qualities to appear in the antigen. I have convincing evidence that contaminated antigen causes false positives in the test. This objection also applies to antigen which is kept for a long time at icebox temperature. In attempting to produce an antigen that would keep indefinitely without deterioration, we tried the following method. Tubercle bacilli and salt in the foregoing proportion were desiccated for twenty-four hours over sulphuric acid. This greatly facilitated the grinding which resulted in an extremely fine white powder. Microscopic examination of smears made from this powder showed that most of the bacilli were fragmented. The powder would keep indefinitely in a sealed tube. The antigen was prepared by dissolving 50 mg. in 5 c.c. of distilled water and either used directly or after forty-eight hours' autolyzation at 38 C. The antigen seemed to give satisfactory results, and one specimen of powder tested after two years' storage at icebox temperature seemed as usable as when first prepared. I was so satisfied with this antigen that I used it for many months in routine tests, and the great majority of the cases here reported were tested with this antigen. However, I noticed that the percentage of known tuberculous cases which gave a negative test was running continuously higher than other workers had reported. In seeking an explanation for this, an antigen was prepared from fresh young cultures of the same strains of bacilli. These were fully virulent and were not attenuated by heating or desiccation. These two antigens were run simultaneously on a series of cases and it was found that the number of positives among known tuberculous cases was distinctly higher with the fresh antigen and that the reactions were more distinct. I have abandoned the dried antigen in favor of that prepared fresh from young virulent cultures. This antigen in a limited series of the cases has given 96 per cent. positive reactions. The results from this antigen will be reported later. The experience with antigen prepared from desiccated bacilli is here reported, but its use is not recommended, since it lacks in delicate antigenic properties.

RESULTS IN ONE HUNDRED AND FIFTY-SIX TUBERCULOUS CASES

There were 156 cases diagnosed clinically as tuberculosis. Of these, 133 cases, or 85.2 per cent., gave a positive test. These were subdivided as follows: Twenty-four cases of incipient tuberculosis were positive in twenty-one cases, or 87.5 per cent.; forty-nine cases classed as moderately advanced were positive in forty-two cases, or 85.7 per cent.; eighty-three cases classed as far advanced were positive in seventy cases, or 84.3 per cent. It is noticed that there is a more frequent occurrence of negative tests in the far advanced cases. This point has been observed by others as discussed above. However, this feature does not seem to have direct value as indicating the degree of the patient's resistance in our experience, as in four cases which terminated fatally, the serum gave a strongly positive test within two weeks prior to death.

There were sixty-one cases in which there was clinical suspicion of tuberculosis, or at least the clinician felt it necessary to consider tuberculosis before making a diagnosis. These cases had no definite evidence of tuberculosis and hence belonged to the class in which this test will probably be of greatest service as an aid to diagnosis. Twenty-four of the sixty-one cases, or 40 per cent., gave a positive test.

There were twenty-three cases which presented other clinical conditions in which tuberculosis was not suspected; six of these, or 26 per cent.. gave positive test.

The Bordet test was applied to 100 serums which were strongly positive by the Wassermann test. Of these, thirty-eight reacted positively. Histories of all these cases were not obtainable, but in view of the recognized frequency of occurrence of tuberculosis in syphilitics, it is probable that many of them were tuberculous. However, it is not fair to assume that all of them were, and I agree with the opinion of others, that a Wassermann test should be made on each serum tested for tuberculosis, and that in the presence of a positive Wassermann test, a positive result with tuberculous antigen should be regarded as inconclusive. This practice has been followed in the series here reported. It has resulted in establishing a positive diagnosis of syphilis in several cases in which tuberculosis, not syphilis, was suspected. An attempt was made to eliminate the positives occurring with Wassermann positive serum, by extracting the tubercle bacilli with absolute alcohol and ether and preparing the antigen from the insoluble residue. Such antigen showed no difference from that containing the whole tubercle bacilli either in tests on known tuberculous serum or on Wassermann positive serum.

There were 100 young healthy adults, for the most part medical students, who submitted themselves as controls. Of these, there were twelve who have positive reactions, on repeated tests. Two of these, on submitting to a careful physical examination without the examiner's knowing the result of the test, were found to have physical signs sufficient to class them as suspicious. Those who have had a wide experience concerning necropsy examinations will substantiate the statement that a high percentage—60 per cent. according to some reports—of adults dying from other causes show evidence of previous tuberculous infection. The opinion is that these small healed lesions were active in early or young adult life. Often the lesions are so small as to escape even the most searching physical examination. Personally, I am of the opinion that it would be difficult to find a group of 100 young adults chosen at random, which would not contain a few members with slight, active tuberculous lesions. It is probable that some of the positives in this group were tuberculous, and that the remainder were false positives due to an imperfect antigen.

CONCLUSIONS

Complement fixation in tuberculosis should be regarded as an established technic, well past the experimental stage. Its value will be greatest as an aid in the early diagnosis of tuberculosis. It should be regarded in the same manner as the Wassermann test, not as a test on which alone the diagnosis may rest, but as evidence which, considered together with other evidence, will be of real value in establishing the diagnosis. Its value will be great or small exactly in proportion to the use made of it by practitioners in an attempt to detect early incipient tuberculosis, and to aid in establishing the diagnosis of doubtful or suspicious cases.

I have found that a freshly prepared antigen containing living virulent bacilli is superior to one containing dried organisms, although the latter will keep indefinitely.

Until some antigen is devised which will not give false positives by fixation with the lipotropic antibodies of syphilitic serum it will be necessary to exclude the presence of the latter by the Wassermann test before basing conclusions on the results. Craig and Miller seem to have prepared such an antigen. I was unable to verify this statement with antigen prepared by Miller's method.

ABSTRACT OF DISCUSSION

Dr. Augustus B. Wadsworth, Albany, N. Y.: There are so many reactions in the complement fixation of the tubercle bacillus that it is difficult to tell just which of the reactions are significant in the diagnosis of the disease. We ought to proceed cautiously and conservatively in accepting all of the results. There has been considerable difference of opinion and considerable difference in the statistics of the results that some observers have had in the course of their investigations. At the time of the early work with the Wassermann test in the diagnosis of syphilis it was not possible, for the purpose of comparison, to use accurately controlled experimental investigations of the reaction of the test based on infection in animals. The Wassermann test was practically established before this became possible, but it is now possible to study the results of these tests of complement fixation in tuberculosis infection by experimentation on animals. The previous work has failed to take into account the value possibly of comparative study in animals. The immunization of animals, not only with the dead tubercle bacilli or cultures, but the study and development of immunity with specific antigens, can be used to determine just what reactions are obtained.

In my laboratory we have taken up the work quite extensively, and, while we have made little progress with it, we have found that it is practical to carry on parallel experiments with animals. I do not know but what we may meet with some insurmountable obstacles, but it looks to me now as though it would be possible to prepare the antigens. I should like to ask Dr. Moon if he has had any experience in his work with animal tests of the antigens which he has used, or tested the reactions that may develop in the serum of inoculated or tuberculosis animals.

Dr. J. J. Seelman, Milwaukee: In the complement fixation test for tuberculosis, just as in the Wassermann test for syphilis, we must consider the findings in connection with the clinical aspects of the case. It would be unjustifiable to make a diagnosis of tuberculosis purely on the findings of a complement fixation test, because the symptoms for which a patient presents himself may have little or no relation to his tuberculous process. We must consider the test merely as an additional symptom which may or may not be of value in arriving at a diagnosis in a given case.

I recently had occasion to review the literature on tuberculosis of the past few years and found only one clinician who, in the discussion of the diagnosis of tuberculosis, mentioned the complement fixation test. This, in view of the fact that for a period of at least two years the test has been on a dependable basis, seemed to me remarkable. What we need now is propaganda to impress on the clinician the value of this test and to teach him how to use it effectively.

Dr. H. J. Corper, Chicago: We have lived through periods when certain observers believed the complement fixation test in tuberculosis was equal to the Wassermann test. We have come now to a period when we seem to be agreeing better than before. In the beginning reports from Craig and Miller and Bronfenbrenner intimated that we did not need clinicians' findings. Petroff, who also at the beginning felt he could make an absolute diagnosis, recently admitted he erred a little on the side of positive results, probably because of his enthusiasm. Miss Lange, with Dr. Krause, obtained results which agreed well with those of Elizabeth Frazer, who was the first to compare the results obtained with a number of different bacillary antigens. Dr. Paul Lewis of Phipps Institute has tried any number of ways and antigens in an attempt to increase the percentage.

The sum total of the findings and conclusions of these observers can be stated briefly: That the complement fixation test in tuberculosis, varying slightly with different observers, does not give more than about 50 to 70 per cent. positive reactions, regardless of what antigen is used. In these experiments there were reported observations with Craig's, Miller's and Petroff's (multiple) antigens. Today tuberculosis workers feel that the complement fixation test in tuberculosis is not an absolute test; that its only value lies, as in most laboratory tests, in giving the clinician aid. The clinician must make a diagnosis with all the data at hand, both clinical and laboratory. Another striking point brought out revealed how cautious we must be in using this test. It is a fact that 10 per cent. of negative clinical cases of tuberculosis (normal individuals) will give positive complement fixation tests for tuberculosis. Therefore, we can only regard this test as a danger sign, and use it guardedly, indicating that the doctor must go further in his observations to see whether he can find anything else to corroborate the serologic diagnosis. It is not as reliable as the Wassermann reaction.

Dr. R. B. H. Gradwohl, St. Louis: My personal experience with this test has been fairly extensive. I have taken the precaution of working with a number of different antigens made by different men and preferably furnished by the men who recommend it. My experience with the test in advanced cases (and it has been the advanced cases with which I have worked particularly—I have not had the opportunity to get hold of many beginning cases) has given, averaging about five antigens, a very low percentage of positives—I think fifty or lower, at least in advanced tuberculosis.

In the last six months I have been working with all of Petroff's antigens, and there is quite a disagreement at times between the results of his antigens. My best results have been with Petroff's glycerin extract, which is quite stable and reliable. Up to the time Petroff was good enough to furnish me with this last antigen, Miller's antigen had been the best. I emphatically oppose the statements of those clinical and laboratory men who have stated that this test can be used as a criterion of arrest of a tuberculous process. It is a valuable test for diagnostic purposes in incipient cases; it has a definite value when negative, but a negative result can neither exclude tuberculosis nor can it prove an "arrest" of the process. The test has a great value within these limitations.

Dr. Carl C. Warden, Ann Arbor, Mich.: I want to ask Dr. Moon two questions. He said that the readings were taken after one-half hour's time. Is that right?

Did hemolysis take place on standing with those reactions which were at that time positive? Did he use as antigen any suspensions of organisms other than the tubercle bacillus?

I ask these questions for this reason: I worked with these tuberculous antigens for a year—antigens prepared by the methods described and many others, including the fat antigens. When we got through we came to the conclusion that while it was possible to produce antibodies in the blood of animals by experimental inoculations there was nothing to show that antibody is present in the human individual at any time during the course of the disease.

The pathology of the disease tends to support this question because the response of the human body to the invasion of the tubercle bacilli is a process wholly different from that of other invasions. We have obtained just as good reactions with suspensions of anthrax bacilli, with an organism obtained from scarlet fever patients, and particularly with lepra bacilli, as we did from any of the tubercle bacilli we used.

Dr. V. H. Moon, Indianapolis: I have had no opportunity to conduct experiments with animals. The experience I cited of Dr. Bronfenbrenner seemed to point to the fact that the animals form antibodies against the tubercle bacilli very early and that late in the course of the disease, as it approaches a fatal termination of the infection, the antibodies disappear.

As to details for the preparation of the antigen, I followed quite closely Dr. Miller's published account of the preparation of it. I used fresh virulent young organisms from twelve different strains of human bacilli and four strains of the bovine type. These were desiccated with salt and then pulverized by grinding. This antigen had fine keeping qualities and I was falsely led to think that it was a very desirable antigen. But it is not so sensitive as that prepared from the freshly grown bacilli without desiccation.

As to the consideration of the amount of evidence or the amount of significance which should be placed on the positive test: We should not regard this as definite evidence that the patient is suffering markedly from tuberculosis any more than we should consider a positive Wassermann test as indicative that the patient is suffering from syphilis. The syphilitic is not immune to the other ills to which the flesh is heir. A man may have other ailments as readily as if he did not have syphilis. If a doctor should ask you to make a Wassermann test in a case and should base his entire diagnosis on your positive Wassermann he might think a patient who was about to die of typhoid was purely a syphilitic. The situation is entirely similar regarding complement fixation in tuberculosis. I agree with the statement that we cannot place absolute reliance on it. But I am convinced that this test will give a much higher percentage of positive results than the figure mentioned by Dr. Corper. A certain percentage of apparently normal persons may give a positive test. As evidence of this I cited the twelve out of 100 medical students who reacted positively. Two of them did show evidence which might be regarded as suspicious of tuberculosis, but it would not be fair to send the remaining ten to the West or the South on a diagnosis of tuberculosis on the strength of this test. This test is merely evidence which the clinician shall weigh in correct proportion with other evidence in making his diagnosis. If he is suspicious of a case as being one of early tuberculosis, if he secures a positive complement fixation test he will have additional suspicion that his case may be one of tuberculosis, but he will not have absolute evidence. We may regard it as absolute if we find the tubercle bacilli in the sputum. That, of course, is a higher grade of evidence than any evidence which may be obtained from serum tests.

I have not tried as antigens bacteria of any other varieties, such as the colon bacillus or the *Bacillus subtilis*. I tested only for antibodies against the tuberculosis antigen.

As to incubation period, I was misunderstood. In making the test, an hour incubation period before adding amboceptor and corpuscles, and an hour incubation after adding the amboceptor and corpuscles was the method followed regularly.

I may answer Dr. Warden's question by saying that occasionally tests were slightly positive in thirty minutes which later cleared up. Usually the result was the same after thirty minutes' reading as it would be at the end of the hour. My readings were all taken at the end of an hour.

Nutritive Value of Dried Milk.—The growth curves of children fed exclusively on dried milk from birth closely resemble the average growth curve of breast-fed children, although at somewhat lower levels by reason of the more delicate condition of these children. The conclusion is reached "that cow's milk, during the process of desiccation, loses none of the characters which are necessary for the support of normal growth in infants." Teething and walking begin at normal ages, and there is no greater liability of rickets and scurvy. The experiments on rats led to the conclusion that dried milk as a sole food maintains the animal in good health and permits normal growth for periods which long outlast those corresponding with infancy and early childhood in the human subject.—Food Report 24, Local Government Board.

ANTHRAX AT CAMP HANCOCK, GA.

JOHN B. LUDY, A.M., M.D. (Philadelphia)
Major, M. R. C., U. S. Army
and
EUGENE C. RICE, M.D. (Washington, D. C.)
Lieutenant, M. R. C., U. S. Army
CAMP HANCOCK, AUGUSTA, GA.

The possibility of the appearance of the skin manifestations of anthrax from time to time is admitted, and the necessity of having a clear idea of the classic picture of an anthrax pustule is therefore apparent.

In reporting three cases of anthrax occurring in this camp within four weeks, we hope to impress on the reader the distinguishing points in diagnosis, and the necessity for early treatment.

Anthrax is definable as a specific and highly contagious disease due to *Bacillus anthracis*.

Fortunately the organism never enters the unbroken skin, but gains entrance at the site of an abrasion. Any commercial animal product—hide, hair or wool—and the articles manufactured therefrom afford the source of contagion.

SYMPTOMS

The usual appearance of the skin manifestations of anthrax is as follows:

Following a period of incubation varying from one to five days, a small red papule appears at the site of abrasion, with symptoms of itching and burning, though these are sometimes absent.

After the lapse of from twelve to twenty-four hours, a small vesicle appears on the papule, surrounded by a red areola and edema. The vesicle ruptures in from two to four hours, its site being marked by a small ulcer exuding a small amount of clear serum.

After from twelve to twenty-four hours, the crater of the ulcer will harbor a carbon-like (coal-like) eschar. Numerous vesicles appear on the edge of the crater.

The classic picture, therefore, would show a black eschar lying in a crater surrounded by vesicles—a red areola and an edema usually out of proportion to the size of the lesion. Some of these symptoms may be wanting, but the black eschar is always present and is diagnostic. The lymphatic glands draining this area are usually greatly swollen.

The subjective symptoms are malaise, fever, headache, prostration, and slight itching or burning at the site of the lesion.

The objective symptoms are early weak, rapid and intermittent pulse; a rise in temperature varying from normal to 105; occasional vomiting and diarrhea; occasional signs of fluid in the abdomen or pleural cavity; early cyanosis, and delirium usually absent or late. Death may, however, suddenly intervene, the symptoms being disproportionate to the gravity of the case.

The "edema maligna" of anthrax occurring about the eyes, lips or neck is characterized by diffuse, painless, semitransparent edema, with vesicles appearing on the surface, some often containing blood. These, however, rapidly disintegrate, and the carbon-like eschar appears. Constitutional symptoms are early and correspondingly fatal.

DIAGNOSIS

The diagnostic points are:

1. Carbon-like eschar from 1 to 3 cm. in diameter, reposing in a crater bordered by numerous vesicles surrounded by a red areola and considerable edema.
2. Absence of suppuration and pain.
3. Systemic symptoms—malaise, headache, fever, prostration.
4. The finding of the *Bacillus anthracis* in the vesicles or edema about the lesion, or the appearance of the organism in films taken from beneath the eschar.
5. The occurrence of a lesion on parts of the body habitually uncovered. These will serve to differentiate anthrax from furuncle, folliclis, carbuncle, chancre, granuloma pyogenicum, phenol or cautery burns and poison wounds.
6. The absence of pain, a diffuse, semitransparent edema covered with vesicles filled with blood or the ulcer harboring the carbon-like eschar, and the finding of *Bacillus anthracis* will differentiate the edema maligna of anthrax from phlegmonous erysipelas, cellulitis or angioneurotic edema.

TREATMENT

As soon as the diagnosis is clinically established and films and cultures have been made, the following procedure should be immediately instituted:

1. The tissues about the lesion should be infiltrated with from 30 to 50 c.c. of antianthrax serum, a large needle and Lüer syringe being used.
2. The lesion should be dissected, a nose cautery being used, and an effort made to remain at least one-half inch from its border.
3. Seventy-five c.c. of antianthrax serum with 50 c.c. of physiologic sodium chlorid solution, should be given intravenously.
4. Seventy-five c.c. of antianthrax serum should be given intramuscularly.
5. The wound should be dressed once in twenty-four hours with a solution of phenol (carbolic acid), 3 parts; camphor, 7 parts; glycerin, 40 parts, and alcohol, 180 parts.
6. The serum therapy should be repeated every eight hours, according as circumstances may require.

REPORT OF CASES

Case 1.—A soldier, admitted, June 7, 1918, noticed a small pimple on the left cheek, June 4. He used a new shaving brush, June 2, and his razor caused an abrasion. June 6, the lesion had increased in size and was described by the patient as a sore with a black center.

June 7, on admission, he complained of headache, fever, malaise and a feeling of dizziness and prostration, which symptoms were the reason for his admission. The temperature at 2 p. m. was 101.2, the pulse, 98. At 4 p. m. the temperature was 104.6 and the pulse, 120. The pulse was fair in volume but intermittent. At 7 p. m. after the laboratory examination had been made the patient was given ether anesthesia, the ulcer was cauterized, and the whole area was excised, the excision going wide of the border of the lesion. The wound was not closed and was dressed with neutral solution of chlorinated soda. No antianthrax serum was obtainable, so 60 c.c. of horse serum with a like amount of physiologic sodium chlorid solution was given intravenously.

June 8, at 8 a. m., an abdominal examination revealed free fluid, and an examination of the chest revealed beginning edema of both lungs. At 4 p. m. the fluid in the abdomen had greatly increased. The temperature was 97.6, the pulse, 160, weak and intermittent, and unaffected by digitalin. At 8 p. m. the patient developed a low type of delirium.

June 9, at 2:15 a. m., the patient died.

Case 2.—A soldier, admitted, June 19, 1918, presented the subjective symptoms of frontal headache, malaise, fever, dizziness and extreme prostration. The temperature was 99.8, and the pulse, 96. No anthrax lesion was noted by the patient or the attendant at the time of admission.

From June 20 to June 22, the symptoms were the same.

June 22, a blister on the side of the neck was noticed. The temperature was 101.4 and the pulse, 88.

June 23, the patient felt a pain in the neck and noticed glandular enlargement in addition to the appearance of an ulcer at the site of the blister of the previous day. A clinical diagnosis of anthrax was made and confirmed by laboratory findings. The temperature was 101.8 and the pulse, 84. At noon, the area about the lesion was infiltrated with 50 c.c. of antianthrax serum, a large needle and a Lüer syringe being used; under ethyl chlorid general anesthesia the lesion was dissected with a nose cautery and the base seared with the cautery, with no bleeding. The wound was dressed with a solution of camphor, phenol and alcohol. Fifty c.c. of antianthrax serum, together with a like amount of physiologic sodium chlorid solution, were given intravenously. At 4 p. m. the axillary temperature was 103.2 and the pulse, 96. At 8 p. m. the temperature was 101 and the pulse, 104.

June 23, at 8 p. m., 50 c.c. of antianthrax serum with 50 c.c. of physiologic sodium chlorid solution were given intravenously.

June 24, at 11 a. m., the temperature was 100.4 and the pulse, 96. Fifty c.c. of antianthrax serum were given intravenously into the gluteal region. At 5 p. m. the temperature was 100 and the pulse, 86. Fifty c.c. of antianthrax serum were given intramuscularly.

June 25, at 9 a. m., the temperature was 98.4, the pulse, 80 and the respirations, 24. Fifty c.c. of antianthrax serum were given intramuscularly.

June 26, no further treatment was given except local treatment. At 9 a. m. the temperature was 98, the pulse, 62; at 9 p. m., 98 and 60.

June 27, at 9 a. m. the temperature was 97.4, the pulse, 50; at 9 p. m., 98 and 52.

June 28, at 9 a. m. the temperature was 97, the pulse, 58; at 9 p. m., 97.4 and 52.

June 29, at 9 a. m. the temperature was 97.4, the pulse, 50; at 9 p. m., 97 and 60.

June 30, at 9 a. m. the temperature was 98.4, the pulse, 60; at 9 p. m., 98 and 60.

July 1, at 9 a. m. the temperature was 98, the pulse, 60; at 9 p. m., 98 and 60.

July 7, the wound was healed in the normal manner. This patient was not at any time delirious. He was nauseated only the first day, and showed no reaction from serum therapy.

His recovery is believed due to the early use of antianthrax serum and the manner in which the lesion was removed.

Case 3.—A soldier, admitted, July 3, 1918, had accidentally cut his right cheek while shaving on the morning of June 30. He had been using a new brush.

July 1, the patient noticed a papule at the site of the cut.

July 2, as stated by the patient, the papule had appreciably increased in size, associated with swelling in the neck.

July 3, the lesion showed a black area in its center. The patient stated that he felt tired, and that he went on sick call because he was worried concerning the rapidly growing ulcer on his cheek. On admission, at 10:20 a. m., the temperature was 100, the pulse, 100. The patient complained of headache, dizziness and nausea. The lesion on the right cheek was one-half inch in diameter and was surrounded by numerous vesicles; in the center was a black eschar. The tissues of the right side of the neck showed considerable tumefaction. The patient did not complain of any pain at the site of the lesion. At 1:15 p. m. the tissues surrounding the lesion were infiltrated with antianthrax serum, and the lesion dissected with a nose cautery. The base was cauterized. This was done under ethyl chlorid general anesthesia. Seventy-five c.c. of antianthrax serum, with 50 c.c. of physiologic sodium chlorid solution were given intravenously. Seventy-five c.c. of antianthrax serum were given intramuscularly into the gluteal region. The wound was dressed with phenol and camphor solution. The temperature was 101.2 and the pulse, 84, at 10 p. m.

July 4, 75 c.c. of antianthrax serum and 50 c.c. of physiologic sodium chlorid solution were given intravenously. Fifty c.c. of antianthrax serum were given intramuscularly. At 9 a. m. the temperature was 97.6, the pulse, 80; at 9 p. m., 100 and 84.

July 5, 50 c.c. of antianthrax serum were given intramuscularly. At 9 a. m. the temperature was 99, the pulse, 82; at 9 p. m., 99 and 74.

July 6, at 9 a. m. the temperature was 97, the pulse, 68; at 9 p. m., 97.6 and 60.

July 7, at 9 a. m. the temperature was 96.6, the pulse, 60; at 9 p. m., 97 and 68.

July 10, the wound was granulating in the normal manner. The pulse still continued to be around 68, but was of good volume, and the patient had no subjective symptoms of any kind.

BACTERIOLOGIC DIAGNOSIS

In view of the ruling of the Surgeon-General of the Army, that diseases of known bacterial origin cannot be diagnosed as such by the clinician until his provisional diagnosis has been confirmed bacteriologically, Case 1 is of interest because of the difficulty encountered in making a positive bacteriologic diagnosis of infection by the anthrax bacillus.

A few hours after the patient had been admitted to the hospital, several films were made from the serum exuding from the vesicles about the circumference of the lesion, but no organisms resembling *B. anthracis* were seen. It was only after the gangrenous central area had been raised by means of forceps and smears made from the underlying tissue that an organism similar to the anthrax bacillus was found. This bacillus was gram-positive and occurred in chains of two or three, the average size being 1 by 7 microns, a few measuring 1.5 by 2.5 microns. The ends of the bacilli were square, and a few appeared to show slight cupping. One or two centrally placed spores were seen. A number of gram-negative, coccoid bacilli and a few pus cells were also seen. Cultures were made on plain and blood agar at the same time that the direct films were prepared. A blood culture was made at this time.

Twelve hours later the cultures made from the lesion were examined, and a large number of gram-negative coccoid bacilli with central nonstaining areas were seen. A large number of the gram-positive bacilli were also present. The majority of the latter were in long chains, the average size being 1 by 4 microns. Very few of these organisms had square ends; the majority were rounded. No spores were seen at this time, but twelve hours later they appeared in large number. An emulsion of the mixed culture was plated for the purpose of obtaining the various organisms in pure culture. No growth was obtained in the blood culture after seventy-two hours' incubation.

Morphologically and culturally, the gram-positive bacillus corresponded to *B. anthracis*, the absence of motility in the hanging drop, the inverted fir-tree appearance of the growth in stab agar cultures, the Medusa head appearance of the colony on agar, etc., being typical. Suspensions of the bacteria in physiologic sodium chlorid solution were boiled for varying periods of time, and the emulsion then plated. It was found that two minutes' boiling was required to kill all organisms in a twenty-four hour culture containing spores.

In determining the degree of pathogenicity of the bacillus, a total of seven animals were used. The results are given in the accompanying table.

In view of the pathogenicity of the organism and its marked similarity to the anthrax bacillus, the clinical diagnosis of infection by *B. anthracis* was confirmed.

No necropsy was performed, but several splenic punctures were made several hours after death with negative results, no anthrax bacilli being found in films or culture. The undertaker reported that on opening the peritoneal cavity a fairly large amount of clear, light brown fluid was found. A firm, dark colored tumor, 4 by 8 cm. in size was found attached to the mesentery of the small intestine. Microscopic examination of sections demonstrated it to be a partially organized blood clot.

PATHOGENICITY OF BACILLUS

Animal	Inoculating Material and Site of Injection	Result
White Rat 1..	Serum from lesion; intraperitoneal injection	No visible effects; animal still living
Guinea-Pig 1..	1.5 c.c. of 12 hour mixed culture* from lesion; intraperitoneal injection	Death after 80 hours; hemorrhagic condition of muscles of thorax and abdomen, viscera somewhat congested; cultures from abdominal muscles and all organs showed motile, gram-negative, coccoid bacilli with central nonstaining area; no anthrax bacilli were present in films from organs or culture; organism responsible for death was a bacillus of the hemorrhagic septicemia group
White Rat 2..	1 c.c. of 24 hour mixed culture* from lesion, second on agar; injected in tail	No visible effects; animal still living
Rabbit 1	1.5 c.c. of 24 hour mixed culture* from lesion; intraperitoneal injection (8 hours prior to injection, 10 c.c. of blood were removed by cardiac puncture)	Death in 2 hours; necropsy 8 hours after death; cultures from all organs and a variety of bacteria were present; bacilli of the hemorrhagic septicemia group predominated; no anthrax bacilli were found in culture; primary cause of death was shock
Rabbit 2	1 c.c. of 24 hour mixed culture,* third on agar; subcutaneous and intraperitoneal injection	Death in 20 hours; peritonitis found at necropsy; bacilli of the hemorrhagic septicemia group were present in pure culture from all organs; death due to hemorrhagic septicemia
Guinea-Pig 2..	1 colony of gram-positive bacilli; subcutaneous injection in abdominal wall	Killed 25 hours after injection; pig was apparently in good health at time of death; muscles of thorax and abdomen were markedly edematous; no other macroscopic changes; pure culture of the same organism as injected obtained from all organs
Guinea-Pig 3..	Same as for Pig 2	48 hours after injection, animal semed to be in normal state of health; death 70 hours after inoculation; necropsy revealed a hemorrhagic and edematous condition of the abdominal muscles about the site of injection; peritoneal cavity contained blood-tinged fluid; pure cultures of the same organism as injected obtained from all organs

* Emulsion of growth on agar slant.

Cultures made of the bristles of the shaving brushes used by the patients were negative for anthrax bacilli.

In the Cases 2 and 3, no difficulty was encountered in making a bacteriologic diagnosis of anthrax infection, for the organisms isolated from the lesions were characteristic and were pathogenic for guinea-pigs, death occurring in twenty-three and twenty-nine hours, respectively.

CONCLUSION

The difficulty in confirming the clinical diagnosis of anthrax infection in the first case was due to two factors, (*a*) the use of animals (white rats) possessing a high degree of immunity to infection by *B.*

anthracis and (*b*) the presence in cultures from the facial lesion, which were used for inoculating purposes, of a bacillus of the hemorrhagic septicemia group, a rare coexisting organism possessing a marked degree of virulence for certain laboratory animals.

It is possible that the bacilli of the hemorrhagic septicemia group exert an antagonistic influence on the growth of *B. anthracis*, and possibly they accounted for the absence of anthrax bacilli in the animals that died of hemorrhagic septicemia. It was noted that the longer the two were grown together, the greater the disproportion between the two, the anthrax bacilli diminishing in number.

Therapeutics

EPIDEMIC INFLUENZA

Under various names, epidemics corresponding to epidemic influenza have occurred at irregular intervals since accurate descriptions have been made of disease. It is likely that at still earlier times this disease was combined and confused with other epidemic disorders, and so did not stand out as an entity until a relatively modern period. In early English literature this disease is spoken of under a variety of terms. Creighton[1] recognizes it under the name "ague," used by the British seventeenth century authors. In 1658, Cromwell died from this disease, when Morton says the country was "one vast hospital." The Italian term "influenza" first came to England in association with the epidemic of 1743, and it has been employed in connection with the great epidemics of 1833, 1847 and 1889-1890.

About 1712 the French term "la grippe" came into use and has been periodically revived ever since. The great pandemics usually originated in the Far East, and gradually extended westward. The rate of human travel and the degree of intercourse between various parts of the world determined the rapidity of the extension. Besides the great pandemics, scarcely a year has passed without local outbreaks which have been classed under the term "influenza." Whether these are identical with the more widespread epidemics it is impossible to say.

The severity of the disease has varied greatly; some epidemics are very mild; others have been severe. Influenza has embraced America in several pandemics. In his remarkable work on epidemic diseases, published in Hartford in 1799, Noah Webster locates the first American epidemic of which he could find an account in 1647. It passed through the whole country and extended to the West Indies. There were between 5,000 and 6,000 deaths in Barbados and St. Kitts. In 1655 a second severe epidemic occurred in America. Benjamin Rush described an epidemic in 1789 in Philadelphia, which was brought there by members of the first Congress, which had assembled in New York. Daniel Drake records a widespread epidemic in the West in 1807.

The history of epidemics of influenza does not differ so much from that of other diseases spread by human intercourse that are usually called contagious. A widespread epidemic follows the introduction of a specially virulent virus, and there follows a general immunity among those of the population who have been infected. As the epidemic dies out, the infection decreases in virulence and only sporadic cases occur. From such cases and probably chronic carriers, local outbreaks occur; but the general immunity prevents any general epidemic. After a period of years a new susceptible population has replaced the immune one, and with the introduction of a fresh virulent virus a general epidemic is again brought about. This would account for the great susceptibility of young persons, and as it is twenty-eight years since the last great epidemic, we should not expect many individuals above 30 years of age to be now affected.

CAUSATION

The causative agent of epidemic influenza has not been certainly recognized. The attachment of the name "influenza bacillus" to a small bacillus described by Pfeiffer in 1892 has been followed by its frequent reception as the actual specific agent. There is, however, much uncertainty as to its etiologic rôle. It is to be hoped that the study of the present epidemic may lead to some certain knowledge regarding the essential cause of the disease. This should enable us to determine whether the endemic cases and those of limited mild epidemics are really identical with the ones observed in the great periodic outbreaks.

COURSE OF THE DISEASE

The cases in the present epidemic begin usually quite suddenly with pain in the head, back, eyes, limbs and joints. With the pains there is great prostration, chilliness and a fever of from 101 to 104 F. The pulse does not become very rapid, and the patient often is drowsy. Vomiting may occur. Sometimes there may be diarrhea, but usually there is constipation. After the disease has become established the mucous membranes of the nose and throat become reddened, and there is sneezing and redness of the conjunctiva. Involvement of the larynx causing hoarseness, and of the bronchi causing cough are common. There is an associated leukopenia or a normal leukocyte count. A leukocytosis points to some complication. The fever gradually falls to normal after a few days and more or less prostration is present during convalescence. A transient albuminuria is frequent. Many of the cases have hemorrhages of the mucous membranes of the nose some of the urethra or bowel.

SECONDARY PNEUMONIA

Not infrequently a lobular pneumonia develops after a few days, and this is responsible for most of the fatalities. The pneumonia differs from the usual picture of pneumonia, in that the temperature may be very slight, and the pulse rate may give little indication of the gravity of the condition. These cases, instead of subsiding, may come down to practically normal temperature for twelve hours; then there may be a sharp rise in temperature, not followed by a chill, backache, boneache, headache or nausea.

About this time there may also be expectoration containing bright red blood. As a rule, twelve or twenty-four hours after the second rise of temperature on physical examination in the lower lung, in a preponderance of cases on the left side, as seen at

---

[1] Creighton: History of Epidemics in Britain, 1894.

Great Lakes, small areas about the size of a silver dollar of typical pneumonic consolidation are found by auscultation. These areas may become marked so that by the second day of the second rise scattered through the lung, probably both lungs, ten or fifteen of these small areas may have appeared. In the epidemic at Great Lakes, if the patient did well these would gradually disappear. They did not resolve as a pneumonia would resolve. The clearing up of the lung after this in the recovered patients was remarkable as to its rapidity. Other cases went on to a typical lobar, massive consolidation, as far as the physical signs were concerned, with dulness, increase in fremitus, typical tubular voice and breathing and all the signs, except that there was not a very marked increase in the pulse rate, and the respirations were not up to this time markedly increased. Cases with almost complete consolidation of the lung, as to the lower lobes, with a temperature of 105, would have a pulse around 100, with respirations 24 or 26. There may be rapidly developing toxemia and vasomotor depression, with death of the patient resulting in many cases.

INCUBATION PERIOD

The incubation period in these influenzas is probably very short, but it is difficult to obtain accurate figures on this point. The disease is probably spread entirely by contact infection, the virus of the disease being disseminated for short distances through droplets driven into the air in coughing and sneezing. Circumstances which favor this means of spread, such as crowding in cars, favor the spread of the disease.

TREATMENT

The treatment of the disease is largely symptomatic. Acetylsalicylic acid or similar remedies may be required to relieve the pain. The acetylsalicylic acid may be given in a dosage of 1 gm. (15 grains) every three hours, as advised by Hewlett, or a smaller dose combined with 0.1 gm. (2 grains) of acetphenetidin, until symptomatic relief is secured. Warm baths may give relief, although in numerous cases seen at the Cook County Hospital hydrotherapeutic methods failed and were discarded. The mouth should be kept clean, and elimination stimulated by the free ingestion of water and hot drinks. The patient should be kept in bed in a well ventilated room until the fever has disappeared. Chilling should be avoided. The latter precautions will do much in avoiding the occurrence of complications.

When pneumonia develops, as indicated by moist râles in the base of the lungs, with or without dulness on percussion, the patient demands particular care. Every effort must be made to provide for an adequate intake of fluids, and for nourishment, which must be given in fluid form to a large extent. Warm packs are often useful, combined with the application of cold to the head. With any indication of failing heart, stimulants are indicated.

In the cases of secondary pneumonia, many of which result fatally, the chief conditions to be combated are the severe toxemia and the vasomotor depression. The toxemia may be combated by the usual methods, getting fluids into the body by mouth or proctoclysis or even by hypodermoclysis. Small doses of epinephrin may be given at the same time. The removal of the toxemia may be aided by securing elimination, giving large doses of salts, such as magnesium citrate, or by the giving of calomel. In severe cases, venesection may prove extremely valuable. If a marked cyanosis occurs, as is frequently the case, this may be combated by the use of oxygen by inhalation, perhaps according to the method devised by Meltzer,[1] or even as has been suggested by Dr. F. Tice, by injection of oxygen under the skin. The prostration is to be combated by the use of the usual stimulants, such as caffein and sodium benzoate, digitalis, strophanthus or camphorated oil, usually hypodermically. The final stages in this pneumonia are frequently a massive exudation into the lungs and bronchi. At the Great Lakes Naval Training Station efforts have been made to combat this by the use of morphin and large doses of atropin, in some cases as much as 0.0025 gm. or 1/25 grain, being used.

Specific measures are not available in the treatment of influenza. With certain identification of the causal agent, we may hope for some specific protective measures, and perhaps for some specific therapeutic serum.

In the absence of a specific virus to be used in immunizing animals, there remains but one source of a therapeutic serum at the present time. This is in the blood of persons recently recovered from the disease. It is quite probable that the blood of convalescent patients contains antibodies for the specific agent of the disease. It would be desirable to inject citrated convalescent blood into the muscles of patients with pneumonia at least. Naturally such blood should be known to give a negative Wassermann reaction. In view of the strikingly beneficial results from convalescent serum in scarlet fever secured by a number of observers, it seems reasonable to try this in influenzal pneumonia, especially as it is devoid of any harmful effects.

PROPHYLAXIS

The measures to be taken to prevent the spread of the disease comprise all those which interfere with the transfer of the infectious materials from the sick to the uninfected. This includes isolation of the patient, and the intelligent use of proper gauze masks by the attendant. In the time of an epidemic, prompt and efficient isolation of the first cases in a community could accomplish much. If this has been neglected and the infection has spread among the population, measures which prevent the coming together of numbers of persons in close quarters are to be employed. The desirability of closing schools in a large city in the presence of an epidemic is a measure of doubtful value. In smaller places this is more reasonable, and the danger of infection when children are outdoors should be less than when they are brought together in a schoolroom.

The Toll of Tuberculosis.—Though the sacrifice of lives in the present war has been so enormous as to make all previous losses on the battlefield appear slight in comparison, it nevertheless appears to be a fact that this frightful war mortality does not greatly exceed, and indeed may be exceeded by, the deaths from tuberculosis under ordinary conditions, if equal areas and periods be considered. In the four years since the war began, the total number of deaths from tuberculosis among the civilian population and in the armies of all the countries engaged has at least approximated the total number of soldiers killed in battle.—Dr. Livingston Farrand.

THE INFLUENZA OUTBREAK

As set forth elsewhere in this issue,[1] widespread outbreaks of acute respiratory infection have occurred at irregular intervals for many centuries. The general clinical manifestations and the complications have been always practically the same. Owing to conditions that are far from being adequately understood, such infection now and again spreads over the world with great rapidity and in a manner that was altogether mysterious and disconcerting until we learned that it never spreads faster than human travel. It seems as if in the course of evolutionary processes there suddenly is liberated a form of infectious agent against which large numbers of people offer little or no resistance and which is transmitted readily from person to person under the most diverse hygienic and geographic circumstances. That the peculiarly subtile nature of these outbreaks was recognized long before the bacteriologic era is indicated by the introduction of the name influenza, which means, literally, influence. The question as to the real nature of this "influence," it must be acknowledged, is not settled definitely. The discovery by Pfeiffer in 1890, at the time of the last pandemic, of the influenza bacillus (*B. influenzae*) in the sputum and respiratory tract of influenza patients seemed, it is true, to have settled the matter. At any rate, Pfeiffer's claim that he had discovered the cause of influenza secured fairly general acceptance except possibly in France.

Since then, however, the influenza bacillus has been found to be present in practically all cases of whooping cough and in a large percentage of the cases of measles and scarlet fever, as well as in tuberculosis and chronic bronchitis. Minor epidemics of acute respiratory infection, clinically regarded as epidemics of influenza, have occurred in which the influenza bacillus was not present regularly in the sputum[2] or the respiratory tract. In such epidemics, as well as in the great pandemic of 1889-1890, streptococci and pneumococci occurred quite regularly in the respiratory tract; indeed, a large group of French and German investigators regarded the great pandemic as a streptococcus or mixed streptococcus and pneumococcus infection. We see that as a matter of fact the only evidence that influenza is caused by the influenza bacillus, up to the time of the present outbreak, is the demonstration by Pfeiffer and others of the presence of the bacillus among other bacteria in the respiratory tract of patients with influenza. The production of influenza in animals by injections of pure cultures of the bacillus has not given any decisive results. No distinctive immunologic reaction has been discovered, showing that the body reacts specifically to the influenza bacillus in the course of influenza. In truth, the evidence in favor of the influenza bacillus is not any stronger or different from that which can be urged in favor of the streptococcus, pneumococcus or other bacteria. And if we grant the possibility that the influenza bacillus may cause outbreaks of influenza, wherein lies the deep difference between such strains of the bacillus and the strains found in whooping cough, measles and other conditions?

The "influence" in influenza is still veiled in mystery. It is also too early to consider in detail the outcome of the etiologic investigations of the present outbreak; already contradictory results have been recorded, and for the present we await further developments. We may anticipate, however, highly valuable and interesting contributions when the full observations on the outbreaks at the Great Lakes Naval Training Station and other military camps, as well as in civil groups, are published. The recent remarkable work on the spread and prevention by selective isolation of streptococcus bronchopneumonia in measles and other conditions in our Army camps sets a fine example, which we believe will be duplicated in connection with influenza.

THE DEFENSE OF CORN AS A WAR TIME FOOD

The United States Food Administration, as we have pointed out, has been particularly careful to fortify its pronouncements and dietary admonitions by reference to the judgment of scientific experts, and has frankly stated that so far as nutritional value is concerned it makes practically no difference whether we eat wheat or oats, rye or barley. Wheat flour, which people are asked to conserve, has just one advantage over the other cereals: it can be made into lighter and more durable bread.

Since our entry into the war, corn has become the most important and popular substitutive cereal. The mill products of maize are rapidly obtaining vogue in the nutrition of large numbers of our population. The value of dependable information is thus manifoldly emphasized. It may rightly be admitted that the maize kernel, by itself, is by no means an adequate or complete food. If we except milk, few individual foods are sufficiently perfect in chemical make-up to satisfy the definition of an adequate diet. Neither sugar nor butter are all sufficient foods when used alone, and no one possessing the rudiments of physiologic education regards them as such. Since it has been learned that corn contains a considerable proportion of a protein which is unquestionably inadequate as the sole source of nitrogen to the organism, this cereal has acquired an unintended reputation of dietary inferiority.

---

[1] Epidemic Influenza, Therapeutics Department, this issue, p. 1136.

[2] Mathers, George: Etiology of the Epidemic Acute Respiratory Infections Commonly Called Influenza, Proc. Inst. Med. Chicago, 1916, 1, 84; Bacteriology of Acute Epidemic Respiratory Infections Commonly Called Influenza, Jour. Infect. Dis., 1917, **21**, 1.

But corn contains more than one protein, and the true value of its combination can be ascertained only by physiologic studies with the products of the entire kernel as it is popularly used, rather than by feeding experiments with isolated proteins. We have already referred to the experiments of Sherman, Wheeler and Yates[1] indicating that the substitution of maize protein for that of wheat to the extent of from one fifth to one third of the total protein intake was found to be without unfavorable effect on the nitrogen balance, whether the test was made by abrupt substitution in a low protein diet, or by ability to maintain equilibrium for a long time on a low protein diet of which the protein was largely that of corn meal. In each of these cases there was some discomfort of digestion attributed at the time to the unaccustomed use of relatively large quantities of corn meal, but perhaps at least equally attributable to the fact that the diet as a whole was too bulky and too starchy for the summer weather in which the experiments were performed.

In later experiments, likewise conducted in Professor Sherman's laboratory at Columbia University,[2] New York, corn meal replaced all other starchy food and actually furnished from 73 to 97 per cent. of the total nitrogen intake. The investigators found that, in the maintenance metabolism, the efficiency of the maize protein was about the same as that reported for the prized wheat. Nitrogen equilibrium was maintained over long experimental periods with a low protein intake, the largest part of which consisted of maize protein. This must not be construed into an argument for the exclusive use of such protein in the dietary of growth, whether it be during adolescence, pregnancy or lactation. It is more than likely that small supplements of other protein foods will greatly enhance the value of the diet. But the lesson of this investigation will be properly presented by quoting in part Sherman's conclusion that certainly one need not hesitate on the score of the protein intake to substitute maize products entirely for the corresponding products of wheat, even when these make up the main part of the food supply. Physicians need to be armed with such opinions when their can't-eat-substitutes-for-wheat patients importune them.

THE REGULATION OF BODY TEMPERATURE

It requires little analysis to discern that the temperature of an object represents the resultant of two factors: the gain of heat from without or within and the loss of heat. The body temperature of an animal may therefore be conceived to represent a balance between heat production and heat dissipation. In some organisms which we term cold-blooded animals, like the frog, the temperature of the body is ordinarily only slightly higher, at most, than that of their environment. Among the so-called warm-blooded animals, including man, on the other hand, the balance is so adjusted that it remains fairly constant for the individuals and the species, despite wide variations in the temperature of their surroundings.

To account for this unique regulatory phenomenon it has become popular within recent years to assume the existence of a special "center" which acts analogously to a thermoregulator. To recall the various precise locations of this hypothetic spot in the central nervous system, which have been postulated since the classic experiments of Aronsohn and Sachs in 1885 on "heat puncture," would take us too far astray in the fields of physiologic literature. Latterly the complications of uncertain location have been increased by the claim of a duality of mechanisms—a thermogenic or heat center and a thermolytic or cold center in the midbrain. The difficulties of those who defend the existence of such well defined heat-regulatory centers are augmented by the fact that any form of experimental stimulation which results in an increase in muscular activity thereby produces an otherwise explicable augmentation of heat; furthermore, the advocates of heat centers have found it difficult to account for the often repeated assertions of experimentalists that large portions of the postulated brain areas can be removed without consequent loss of temperature regulation.

Thus the problem under consideration has been left in great uncertainty—in that state in which textbooks marshal the significant evidence for and against a hypothesis and leave to the reader the discovery of the true solution. In such cases the only hope of success lies in the acquisition of new facts such as have recently been contributed by Lillian M. Moore[1] from the Spreckels Physiological Laboratory of the University of California. She has directed her attention to the corpora striata, the favored location of the centers. Puncture of this portion of the brain, the classic method of stimulation, was not attended by hyperthermia in more than a few cases out of many trials. Furthermore, she found that after removal of the caudate nucleus in rabbits and the cerebral hemispheres in pigeons—both warm-blooded species—a normal body temperature still was maintained. Evidently, then, the corpora striata are not essential for the maintenance of a constant body temperature. As this research offers no confirmation of the existence of special "heat centers" in the brain we may well ask whether the regulation of temperature is perhaps accomplished in some way analogous to that of blood pressure reaction, osmotic pressures, etc., in the organism. The uniform behaviors of these are not ascribed to specific centers, but have been attributed to equilibrium reactions involving physicochemical phenomena. The correct solution of the question of temperature regulation is of more than academic interest to the physician who is desirous of understanding the scientific basis underlying his use of antipyretic drugs as well as the genesis of fevers.

---

Physiol., 1918, **46**, 24; II, Relation of the Corpus Striatum to the Regulation of Body Temperature, ibid., 1918, **46**, 253.

THE SIGNIFICANCE OF URINARY AMMONIA

Among the nitrogenous constituents of the urine, derivatives of ammonia are practically always present. Under normal conditions the quantity of ammonia thus eliminated by a healthy adult is not large; it usually amounts to less than half a gram per day. In certain diseased states, however, multiples of this quantity may be found in the urine. We do not refer here to the ammoniacal urines that result from bacterial decomposition of urea in the bladder and genito-urinary passages, but rather to a metabolic component directly secreted by the kidneys.

There was a time, not many years ago, when this ammonia in the urine was looked on as the result of a pathologic disturbance in urea formation. In consequence of the deaminization of amino-acid complexes, ammonia is presumably continually being formed in the body and promptly synthesized into the characteristic final end-product of nitrogenous metabolism, urea. It is easy enough to suppose that an upset in the later stage would leave the precursor of urea to be eliminated as such. A growing mass of experimental evidence has made it seem more than doubtful whether the urea-forming function is ever so severely impaired. Indeed, it appears to be efficient under many tested conditions of severe tissue damage. A better explanation of the appearance of ammonia has been afforded by the indication that it serves to neutralize acid either formed in the body by metabolic processes or introduced as such.

A classic research by Janney[1] has made it probable that the ammonia in the urine has as its sole function the neutralization of acid products and ceases to be formed in the presence of an excess of fixed alkali. He gave sodium bicarbonate or citrate to men and found that the quantity of ammonia in the urine was reduced to almost undeterminable traces. If any doubt as to the significance of the results remains, it must be dispelled by the latest contribution to this subject. Denis and Minot[2] of the Massachusetts General Hospital have found that it is not possible in normal subjects to obtain urines absolutely ammonia-free by the long continued administration of alkalis. But when the test is made on nephritics under comparable conditions of diet, even the last traces of ammonia disappear. Evidently the nephritics retain the drug for a longer time, thus allowing the alkali more time to exert its neutralizing effects. This is substantiated by the actually demonstrated lag in the excretion of the excess of the carbonate. As further indication of the rôle of acids formed in the metabolism of protein, it was observed by Denis and Minot that during periods of high protein feeding less than 50 per cent. of the ingested alkali was recovered, whereas after diets lower in protein the percentage of recovered bicarbonate amounted to nearly 90. There is no reason today for believing otherwise than that the sole function of the ammonia found in the (undecomposed) urine lies in the neutralization of acids arising during the normal metabolic process.

Current Comment

FOOD CONSERVATION FOR 1918-1919

Mr. Hoover, as food administrator, has given our allies the notable message of President Wilson, telling them that we will eat this year at a common table with them, and has pledged the American people to add an additional 5,000,000 tons to the 10,000,000 tons we sent last year, or 15,000,000 tons in all. We are to eat a common war bread with them made with a 20 per cent. substitution of flours from other grains mixed with that from wheat. The people of France, Great Britain and Italy have learned how to use substitutes so well that we can send them our quota from any of our durable foods. The bountiful wheat harvest will meet the present war needs and permit of the storage of a reserve for emergencies or against a short crop next year if we are all wise and careful. We dare not again see the national flour barrel as it was last summer when, just before the new crop came in, we had only ten days' supply in the country. Our margins must not be so narrow hereafter, particularly as we decrease our productive man power to build up the Army. Conservation for the coming year, aside from sugar, will probably be less dramatic than last year with its "wheatless days" and "meatless days," but it will have to be even more intense than before. All must reduce their intake to the physiologic limit that permits of the necessary hard war work. There must be no waste, less must be bought and less consumed, and the clean plate of our New England ancestors must again be the symbol of American thrift and American endeavor to serve by saving. Physicians must needs more and more advise their patients as to the use of foods and of the amounts actually needed for health. They can become active and sane exponents of the national food conservation program. The great results from the voluntary savings of the past year show the high intelligence and sensitive conscience of the American people. The majority of them need only to be told what to do. With our allies and ourselves at the common table, with the gross division of our food supplies based on the fundamental needs of the body in calories, the physician, reaching as he does into innumerable homes, has a new and inspiring opportunity for that guidance that should be his right because of superior knowledge.

THE PROPAGANDA OF THE V. M. S. C.

The latest Press Bulletin issued by the Volunteer Medical Service Corps, just received, consists of a letter of transmittal, "To the Editor," signed by the Assistant Secretary of the General Medical Board; an "Official Announcement" from the President of the V. M. S. C. and the Chairman of the General Medical Board; and five foolscap pages in the form of questions and answers concerning the V. M. S. C. This Bulletin seems to have been issued to emphasize what the name of the organization indicates—that is, that this society is purely voluntary. To quote from the "Official Announcement":

> No official or committeemen representing the Volunteer Medical Service Corps or the General Medical Board of the Council of National Defense is now authorized or has been authorized to favor any organized or unorganized method of coercion in inducing members of the medical profession to join the Medical Corps of the Army or Navy, or the Volunteer Medical Service Corps. Our committeemen are especially urged against favoring any movement that would threaten to impair a medical man's standing in his local, state or national society because he refused to enroll in the Army or Navy, or the Volunteer Medical Service Corps.
>
> It must be made clear that the Volunteer Medical Service Corps is a volunteer organization which has for its object the enrolment and classification of the profession.

The Journal is glad that there is to be a change in the propaganda in the procedure of building up this organization. Our profession is no longer to be threatened and coerced into it, as has been the case, especially during the more recent "drive" since the reorganization on August 2. Not only have physicians been threatened with having their names published in the newspapers, thus publicly branding them as "slackers," but the methods of promotion of this society finally reached the stage in which physicians who were not commissioned and who did not join this organization were threatened with loss of membership in county societies.[1] The medical profession is to be congratulated that these coercive measures are no longer to be employed. The general and hearty response of physicians from the time we entered the war to every call for the service should have forbidden the employment of measures which reflect on our profession and which the V. M. S. C. itself is now forced to decry.

UNCERTAINTY REGARDING PREMEDICAL STUDENTS

There is considerable confusion in colleges and universities regarding the courses for premedical students, but definite instructions on this point have not as yet been sent out. Paragraph 3 of the circular letter from the Committee on Education and Special Training, of August 28, specifically says that "the student soldiers will be given military instruction under officers of the Army and will be kept under observation and test to determine their qualification as officer-candidates, and technical experts such as engineers, chemists and doctors." This indicates that the committee had not forgotten the importance of safeguarding the supply of physicians. The circular letter in regard to curricula, however, makes no provision for premedical education. Five programs of instruction were prescribed, these being to prepare students for the five following services: A, Infantry, Field Artillery and Heavy Coast Artillery; B, Air Service; C, Ordnance Corps and Quartermaster Corps; D, Engineer Corps, Signal Corps, and Chemical Welfare Service, and E, Transport Service and Tank Service. Program D, which was arranged for engineers, the signal corps and chemical welfare service, might readily provide also for premedical education if the Committee on Education and Special Training would permit it. If special instructions are intended regarding premedical students they should be issued at the earliest possible moment. Otherwise premedical students will be forced to enter one of the five forms of service referred to above and confusion may result.

THE ORIGIN OF CERTAIN ANEURYSMS

It has been noted as a seemingly remarkable result in studies of experimental pathology conducted by Halsted[1] at the Johns Hopkins Medical School that, after constriction of large arteries in suitable degree by metal bands, a dilatation of the blood vessel occurs distal to the obstruction rather than proximal to it and where it might have been expected. Halsted believes that this helps to explain in a measure the not uncommon occurrence of aneurysms of the subclavian artery distal to a cervical rib. In an analysis of 525 clinical cases of cervical rib, 106 were found in which the subclavian had been compressed; and in twenty-one of these, aneurysm or dilatation of this vessel distal to the site of constriction had been noted. The attempts to explain the phenomenon have assumed as a possible cause either weakening of the wall of the artery from erosion by the rib, variable or intermittent pulse pressure occasioned by the normal excursions of the arm, or vasomotor or vasa vasorum disturbances leading to modified nutritional conditions in the wall of the vessel. Halsted is inclined to reject these explanations. He believes that what he describes as the abnormal, whirlpool-like play of the blood in the relatively dead pocket just below the site of the constriction, and the lowered pulse pressure may be the chief factors concerned in the production of the dilatation. The validity of this conclusion must be established before a rational method of cure can be instituted in the management of such aneurysms.

---

[1] As an illustration the following notice appears in the Bulletin of the Buchanan (Missouri) County Medical Society, Sept. 17, 1918:

Notice is hereby given that at the coming meeting of the society the following resolution will be introduced in accordance with request from the National Council of Defense, Medical Section.

Resolved that, (a) After November 1, 1918, applicants for membership in the Buchanan County Medical Society shall be rejected unless they are members of the Medical Reserve Corps of the Army or Navy, or of the Volunteer Medical Service Corps.

(b) The membership of any physician in this society who is not a member of the M. R. C. of the Army or Navy, or of the V. M. S. C. shall terminate as soon after Nov. 1, 1918, as his membership for the current year expires.

Medical Mobilization and the War

Work of Advisory Boards

A telegram addressed to all draft executives calls attention of Local Boards to Section 123 as amended and as appearing in the second edition of the Selective Service Regulations and to the fact that a registrant no longer has the right or privilege of applying to be sent to a Medical Advisory Board.

Women Physicians Wanted for Anesthetic Service

Dr. F. H. McMechan, secretary of the Interstate Anesthetists and the American Anesthetists, Avon Lake, Ohio, states that he is authorized to secure qualified women physicians under 45 years of age as anesthetists for war service. Women physicians desiring to enter this service may communicate directly with Dr. McMechan.

Gas Hospital Unit Starts for France

The first hospital unit designed exclusively for gassed victims has started recently for France. This unit is the unit of the Women's Overseas Hospitals. The chief of the medical staff is Dr. Marie Louise Lefort, New York City, and with her are associated Dr. Adah McMahan, Lafayette, Ind., Dr. Irene M. Morse, Clinton, Mass., Dr. Elizabeth A. Bruyn, Brooklyn, and Dr. Alice M. Flood, New York City. The hospital has accommodation for 300 patients, the equipment is mobile, and has for its immediate needs, two ambulances, one 3-ton truck and one 2-ton truck.

Division Surgeons Appointed

Lieut.-Col. William T. Cade, Jr., has been appointed division surgeon at Camp Sherman, Chillicothe, Ohio; Major William W. Pretts has been appointed sanitary inspector, and Lieut. Harry H. Sumner, assistant to the division surgeon.

Lieut.-Col. James F. Johnston has been appointed division surgeon at Camp Wadsworth, Spartanburg, S. C.; Major Thomas W. Maloney has been appointed inspector, and Lieut. John F. Schafmeister, assistant to the division surgeon.

Lieut.-Col. John J. Roddy has been appointed division surgeon at Camp Cody, Deming, N. M.; Capt. Alvin M. Fortney has been appointed sanitary inspector, and Lieut. L. M. Spalding, assistant to the division surgeon.

Officers' Uniforms Available Through Quartermaster's Department

A general order makes the following announcement relative to the supply of officers' uniforms:

> III. Section IV, G. O. 56, W. D., 1918, is rescinded and the following is substituted therefore:
>
> 1. The following cloths are adopted as standard for officers' uniforms, and all uniforms for officers made in the United States after Dec. 31, 1918, will be one of these prescribed standards:
>
> For coat and breeches, summer wear in the United States and in the tropics only: a, an O. D. cotton; b, a 13-ounce all wool worsted gaberdine. For coats, breeches and overcoats: a, a 12-ounce worsted serge; b, a 16-ounce worsted serge; c, a 16-ounce whipcord; d, a 21-ounce whipcord or elastique; e, a 20-ounce melton. For riding breeches: a, a 23-ounce Bedford cord. For overcoats: a, a 32-ounce melton or kersey.
>
> 2. The quartermaster corps will after Dec. 1, 1918, carry a supply of these cloths, and officers can purchase their personal requirements at the government prices. Samples of cloths with the issue prices will be kept on hand by all camp, cantonment and post quartermasters and may be examined by officers on request after the date mentioned. For the present stock will be carried at the following depots only, but this list will be extended from time to time as cloth becomes available: New York depot, Washington depot, Atlanta depot, Sam Houston depot, San Francisco depot, Chicago depot, St. Louis depot.
>
> 3. The quartermaster general will determine by thorough investigation a schedule of fair prices for making uniforms, including all necessary trimmings, linings, etc., but not including the cloths, and prepare a list of responsible tailors who agree to make uniforms for officers at the schedule rates, the quartermaster general guaranteeing to the tailors the collection of bills for all uniforms ordered through the representatives of the quartermaster general. The schedule of prices, the list of tailors agreeing to make uniforms at these prices and the regulations governing the sale to officers of the standard cloths, the placing of orders, the acceptance of uniforms ordered and the payment of bills will then be published to the service.
>
> 4. The quartermaster corps will arrange to supply from stock at cost made up (ready to wear) officers' uniforms. These will be provided in only two types of cloth for coats and breeches, namely: The 12-ounce worsted serge and the 20-ounce melton and 32-ounce melton for overcoats. It is expected that an adequate supply can be provided at the principal depots mentioned in Paragraph 2 by Nov. 1, 1918, and later at other depots and camps.

The Epidemic of Influenza in the A. E. F.

The *Weekly Bulletin* of the Medical Service in the American Expeditionary Forces contains the following statement relative to the epidemic of influenza. "This disease which was mentioned previously as 'Three Day Fever' is now known to be due to the true Pfeiffer bacillus, although evidently of a much milder strain than the type which prevailed in the pandemic of 1889. This epidemic, though of remarkable mildness in the two months from April 15 to June 15, has within the past four weeks shown certain characteristics which indicate the kind of increasing virulence with which bacteriologists are familiar in the case of strains of pneumococcus passed rapidly through a succession of susceptible animals such as the rabbit. Onset with temperature of 104, projectile vomiting, severe headache, Kernig's sign and high tension spinal fluid, flowing freely up to 100 c.c. has not been uncommon and many cases have been mistaken for, and some have been treated as, meningitis with antimeningococcus serum. No harm, apparently, has come from the use of the treatment and symptomatic relief has often followed the withdrawal of the excess fluid, but confusion is likely to arise when the fluid clear on the tap becomes turbid with leukocytes from the reaction following the introduction of the antimeningococcus serum. If the meningococcus is not found on smear or culture it is well to be satisfied with withdrawal of fluid and not to give serum. Pneumonias have been more common sequelae in July than in April.

Prompt hospitalization effectively guards against serious sequelae and is still the best treatment to be offered. Relief from headache by aspirin, abundant use of water internally, gentle laxative, and, when the temperature has fallen, a nourishing diet, have seemed to be the approved treatment. The same warning should be given now as always in treating influenza, that is, warn against premature return to hard work. The epidemic is about at an end so far as A. E. F. troops are concerned and has been throughout of a benign type, though causing considerable noneffectiveness."

Medical Teachers Registered Under Selective Service Act

A circular letter from the Committee on Education and Special Training sent on Sept. 19, 1918, to all institutions having units of the Students' Army Training Corps.

1. Men heretofore or hereafter classified in Class I, Group A, and called to military service will not be granted furloughs.

2. Teachers who are essential are eligible to claim deferred classification under Section 80, Selective Service Regulations, and they are encouraged to do so. Such deferred classification should be claimed for them by the educational institutions by which they are employed.

3. Teachers who are denied deferred classification by the district board and who are liable to call to military service will be encouraged to request voluntary induction in the unit of the S. A. T. C. stationed at the institution where such instructors are employed.

4. In very exceptional cases and on the recommendation of the educational department of the committee teachers who have already been drafted and are now at mobilization camps will be transferred back as soldiers on active duty to the unit of the S. A. T. C. where needed; provided such instructors do not object to return as soldier instructors, have not been permanently assigned in a capacity wherein their ser-

vices will be of great value to the Army, and have not already been designated to attend officers' training schools.

5. Since the colleges are under contract with the War Department to train enlisted men in the U. S. Army, essential teachers are obviously engaged in occupations that are strictly "necessary to the maintenance of the military establishment." It is, therefore, expected that the really essential professors and teachers will be granted deferred classification under the new law on this account. Heads of institutions should see to it that district boards and their industrial advisers are fully informed of all the facts in every case.

Disease Bulletin for A. E. F.

Some interesting notes regarding the Medical Service for the American Expeditionary Forces appear in the weekly *Bulletin of Disease*, September 9, published by the chief surgeon, A. E. F.:

Gas Fright in the Fifth Division.—In a recent attack 251 patients were sent to the field hospital as gassed cases. It was found that over half of these were not sufficiently gassed to require evacuation. It is pointed out the greatest discretion must be used by surgeons in sorting these cases. Where concentrated gases are employed, short exposure only is required to produce severe poisoning. When gases are highly diluted the men may be exposed for some time and still be able to continue on duty. Many men are suffering, not from gassing, but from gas fright. All they need is reassurance. Surgeons must base their diagnoses on physical sense rather than on statements made by patients: place more reliance on statements made by the patient's lungs than on statements made by his mouth.

Influenza Epidemic in the 37th Division—Spitting.—An inspection of this division showed that some men were billeted in an ill ventilated and dusty loft over a stable. The men were working long hours under pressure and returned at night always fatigued and wet from their work in the dugouts. The first cases occurred on July 28, the third case on August 7, and fourteen cases between August 9 and 13. The daughter of the woman who owned the billet fell ill with the disease and the mother made the significant remark that she felt that her daughter had been infected because of the terrible American habit of spitting; that her courtyard had been kept constantly wet by the spitting of the men billeted in the stable. This was an interesting commentary on one of the few but, nevertheless, very serious breaches of hygiene practiced by American troops. It was recommended as a result of this inspection that an effort be made to start a campaign of education to diminish the spitting habit among troops.

Trench Foot.—This is largely a matter of discipline. The cause is constant standing in wet places and impairment of the circulation. Twenty-four hours is the limit for a tour of duty in a water logged trench. Rubber boots are useful when actually working in the trenches, but they are to be used only for this purpose and are to be removed when the necessity is passed. Rubber boots are not suitable for dry cold. If trench foot develops in a command the commanding officer is to be grilled on the following questions, in the form of a report which he makes out every time for each man acquiring trench foot: (1) frequency of baths; (2) frequency of change of socks; (3) length of time on duty and where; (4) condition of trenches; (5) efforts made to improve trench conditions; (6) reason for failure to attain improvement; (7) were unfavorable conditions reported? if not, why? (8) with what result? (9) condition of dugouts; (10) condition of other men of platoon.

This army evacuated in 1915-1916, 3,311 trench foot cases. In 1916-1917 there were 395 evacuated for this trouble. This is due to better care of the feet and better trenches. One should remember always that in the case of trench foot you should use antitetanic serum.

Notes on Venereal Disease from Base Section No. 2.—

	Prophylactic Treatments Given		New Cases V. D.	Cases Developing Following Failure to Take Prophylaxis
Total white troops.....	76,011	4,959	95	37
Total colored troops....	11,008	1,611	41	23
Since organization of B. S. No. 2 there have been		93,343	2,549	1,025

Watch Out for Imported Cooties.—We have enough of the European varieties for experimental purposes. On a transport arriving recently in one organization there were the following number of cases of well established pediculosis pubis: 338th Labor Battalion, Co. A, 22 cases; Co. B, 26 cases; Co. C, 37 cases; Co. D, 27 cases.

Missing

Lieut. Leonidas Barkdull Faulk, M. C., U. S. Army, Monroe, La., is reported in the Official Bulletin of July 5, to be missing in action.

In Captivity

Notification has been received of the capture of Capt. Arthur A. Mitten, Milwaukee, at Fismes, August 4.——Dr. Howard F. Kane, Washington, D. C., on duty in the British Expeditionary Forces, is reported to be a prisoner at Rastatt, Germany.

Wounded

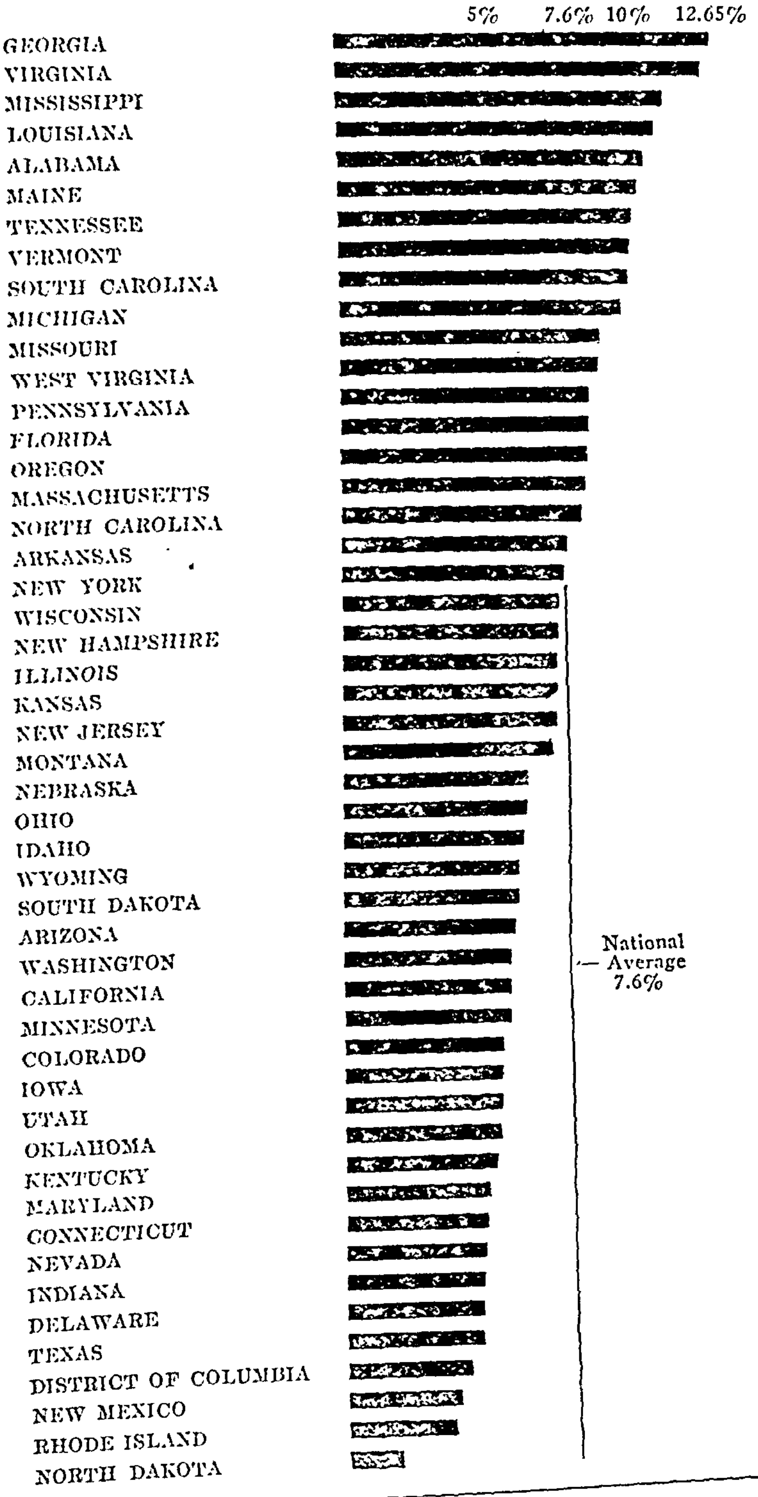
The following medical officers are reported to have been wounded: Lieut. Wesley Lewis Boyden, M. C., U. S. Army, Seymour, Wis., September 6, severely; Lieut. William Wallace Dodge, M. C., U. S. Army, Washington, D. C., severely; Capt. James V. Nelson, M. C., U. S. Army, Logansport, Ind., severely; Lieut. Hugh Rannell Hildebrant, M. C., U. S. Army, Dundee, Mich., severely; Lieut. William Edwin Park, New Milford, Pa., degree undetermined; Lieut. Fred B. Shaffer, Somerset, Pa., wounded in the head; Lieut. William E. Lawhead, U. S. Navy, on duty with the Marine Corps, severely; Lieut. Finis E. Rushing, Coalgate, Okla., degree undetermined; Lieut. Charles A. Jenkins, M. C., U. S. Army, Willimantic, Conn., wounded and gassed; Lieut. Charles C. Ryan, Republic, Pa., slightly; Lieut. Holland T. Ground, Virginia, Minn., severely; Lieut. Shores Erastus Clinard, Sorrento, Fla., degree undetermined; Lieut. Raymond Gene Tuck, Marlette, Mich., severely; Lieut. Frederick J. Cullen, Naparine, Wash., severely.

Awards for Valor

The Distinguished Service Cross has been awarded to Lieut. Thomas M. Barber, M. C., U. S. Army, on duty with the infantry. "On May 28 to 30, 1918, near Cantigny, France, he repeatedly demonstrated heroic self-sacrifice by caring for wounded under enemy fire and with apparent contempt for his own safety. When his aid station had been destroyed by shell fire he promptly moved into a shell hole nearby and continued his faithful work."——Lieut. Frank H. McGregor, M. C., U. S. Army, Mangum, Okla., has been awarded the British Medal for bravery.——Major John T. Barbee, M. C., U. S. Army, Jackson, Tenn., has been decorated for bravery.——Major Wilbur M. Phelps, Staunton, Va., has been awarded the Croix de Guerre.——Capt. Alson J. Hull, M. C., U. S. Army, Williamstown, Mass., has been awarded the British Military Cross.——Lieut. William A. Toertmeyer, M. C., U. S. Army, Cincinnati, has been awarded the Distinguished Service Cross. "At the battle of Cantigny, France, May 28-30, 1918, he readily, on his own initiative, left the security of the trench to administer first aid under fire and in full view of the enemy snipers and machine gunners. His brave conduct was a noble example and his ministrations relieved suffering and saved lives."——Private John B. When, medical department, assigned infantry, has been awarded the Distinguished Service Cross. "For three nights at Cantigny, France, May 28 to 30, 1918, he worked unceasingly under fire, bringing the wounded to safety, ministering to them under his own initiative. He repeatedly left shelter to help wounded men."——Private Frank J. Reynolds, medical department, assigned infantry, "During the fight of Cantigny, France, May 28 to 30, 1918, while acting as stretcher bearer, he constantly and fearlessly exposed himself to machine gun fire to attend wounded, frequently under his own initiative when he might have remained in shelter himself."——Lieut. Leo J. Crum, M. C., U. S. Army, Kalamazoo, Mich., has been cited in orders. At Cierges he had his first aid station in a house at the extreme edge of the village under continuous shelling and was successful in evacuating all his patients.——Drs. Mary Lee Edward, Caroline Sandford Finley, New York City, and Anna I. Von Sholly, Flushing, N. Y., have received the Croix de Guerre from the French government for "excellent surgical work performed under heavy barrage in France."

REJECTIONS AT CAMPS FOR PHYSICAL DEFECTS

The subjoined chart and table, prepared at the office of the Provost Marshal-General, indicate the relative number of registrants inducted and rejected in the various states for the period from Feb. 10 to September, 1918 (date checked):



RECORD FROM FEB. 10, 1918, TO DATE INDICATED

United States	Inducted	Accepted	Rejected		Date Checked September
			Number	Per Cent.	
Alabama	36,845	33,054	3,791	10.29	10
Arizona	3,309	3,116	193	5.83	6
Arkansas	33,339	30,782	2,557	7.67	11

To Fort Riley for instruction, Lieut. P. G. McCABE, Dotyville.

Wyoming

To Raleigh, N. C., as camp surgeon, from Western Department, Lieut. F. H. SPARRENBERGER, Fort Yellowstone.

Medical News

(Physicians will confer a favor by sending for this department items of news of more or less general interest; such as relate to society activities, new hospitals, education, public health, etc.)

ARKANSAS

District Meeting.—The Tenth District Medical Association met at Fort Smith, September 17. In addition to the regular program a surgical clinic was conducted by Dr. Harry C. King at the Sparks Memorial Hospital.

CALIFORNIA

Hygiene Bureau Established.—The state board of health has created a bureau of child hygiene to study the child health of the state, to cooperate with existing agencies now devoted to that cause. Miss Amy D. Steinhard has been placed in charge of the bureau.

New Laboratory Established.—A building for a research laboratory and clinic is to be erected at the Cottage Hospital, Santa Barbara, similar in its exterior architecture to the other buildings. It will be known as the Memorial Laboratory and Clinic for the Study and Treatment of Nephritis, Shock, and Diabetes, and will be under the care of Dr. Nathaniel Bowditch Potter. It is expected that the building will be ready for occupancy early next year.

Personal.—Dr. J. Perry Lewis, San Diego, who has been ill in the Agnes Hospital on account of septicemia, is reported to be improved.——Dr. William W. Crawford, formerly health officer of San Diego, has been appointed a member of the state board of health.——Capt. Theophilus C. Robinson, Los Angeles, who recently entered the Medical Reserve Corps, was operated on at Fort Riley, Kan., September 6, for the removal of a tumor of the bladder, and is reported to be making satisfactory progress toward recovery.——Dr. Reginald S. E. Murray, San Jose, has been gazetted captain in the Canadian Expeditionary Forces.

ILLINOIS

College Suspended.—Reports state that the Hahnemann Medical College and Hospital of Chicago has suspended for the duration of the war.

Red Cross Commission to Greece.—Drs. Samuel J. Walker, Chicago, and Charles B. Gibson, Chicago, are members of the Red Cross Commission that has started for Greece.

State Conference of Charities.—The Department of Public Welfare announces that the State Conference of Charities and Correction will be held at Decatur, October 25 and 27; that the Charity Organization Federation and State Probation Officers' Association will meet, October 24, and that the State Association of County Home Superintendents will hold its annual meeting, October 24 to 26.

Personal.—Major Milton Mandel, M. C., U. S. Army, has been relieved from duty with Base Hospital No. 12, and has been appointed senior division consultant in general medicine to the Second Army Corps.——Dr. Jonathan L. Wiggins, East St. Louis, has been appointed by the director of the Registration and Education of the State of Illinois a member of the examining committee of medicine in place of Dr. Carl E. Black, Jacksonville, who has resigned to go abroad with the Red Cross commission to Greece.

Licenses Revoked.—An official notice from the Department of Registration and Education of Illinois states that, September 24, the license of Dr. Charles E. Cessna, Oak Park, was revoked because of his connection with an alleged quack concern—the J. Russell Price Company of 9 South Clinton Street, Chicago. At the same time the department revoked the license of Dr. Edward D. Porter of Indianapolis, Ind., for having loaned his Illinois certificate for a specified sum to Mr. Emil Pelisher for use in an office in Joliet. It appears that Mr. Pelisher had been conducting a chain of doctors' offices. The license of Dr. George W. Farver of Hammond, Ind., was revoked recently for a similar offense.

INDIANA

Addition to Tuberculosis Camp.—Former Mayor Boehne has given to the Vanderberg County Antituberculosis Society an additional building for the Boehne Camp which will accommodate forty patients and in case of emergency sixty patients. The estimated value of the camp is now $52,000. With the completion of the new building the camp will be able to care for 110 patients. The new hospital is 151½ feet long, 28½ feet wide and will contain besides the schoolroom and wards, dressing rooms, toilet rooms and other facilities.

Child Welfare Work.—Under the auspices of the Child Welfare Committee, Marion County Council of Defense, consisting of Drs. Jane M. Ketcham, chairman, Edgar F. Kiser, Walter D. Hoskins, Charles O. McCormick and J. Don Miller, all of Indianapolis, there were held during 1918 in Marion County 212 clinics for children, at which 5,304 children were examined and 17,000 children enrolled. Of those examined there were 3,058 children of normal weight, 3,859 children of normal height and 2,858 with no defect. Ninety-seven physicians volunteered services for this work. Follow-up work is to be done and four additional weekly clinics are to be held for children of from 2 to 6 years of age. A report of all defective children has been put into the hands of the Public Health Nursing Association and all such children are to be visited at regular intervals.

New State Officers.—At the annual meeting of the Indiana State Medical Association held in Indianapolis, September 25 to 27, under the presidency of Dr. J. Rilus Eastman, Indianapolis, the following officers were elected: president, Dr. William H. Stemm, North Vernon; vice presidents, Drs. Lindsay C. Whiteside, Franklin, Stephen B. Sims, Frankfort, and Henry B. Hill, Logansport; secretary-treasurer, Dr. Charles N. Combs, Terre Haute (reelected); delegate to the American Medical Association, Dr. J. Rilus Eastman, Indianapolis; alternate, Dr. Miles F. Porter, Ft. Wayne, and councilors, first district, Dr. James Y. Welborn, Evansville, third district, Dr. Walter J. Leach, New Albany, fourth district, Dr. August G. Osterman, Seymour, fifth district, Dr. Spencer M. Rice, Terre Haute, ninth district, Dr. William R. Moffitt, West Lafayette, and twelfth district, Dr. Elmer E. Morgan, Ft. Wayne. Indianapolis was chosen as the next place of meeting.

LOUISIANA

State Clinics.—Arrangements are being made for the establishment of municipal, parish, and state clinics for the treatment of communicable diseases in Shreveport and other principal cities of the state.

New Home for Sanatorium.—Plans for a new building for The Pines, the Shreveport sanatorium of the antituberculosis league, have been completed and ground will be broken this month. The building will be located on a site of 54 acres, 8 miles from Shreveport.

MARYLAND

Epidemic of Influenza Under Control.—Although the number of cases of influenza in the military camps around Baltimore is increasing, it is increasing very slowly and the medical authorities, both of the government service and the state and city, are of the opinion that they have the situation under control and that there is no great danger of an epidemic in the city. Two hundred cases have developed at Camp Holabird, at the Curtis Bay ordnance depot and at the Quartermaster's station at Riverview, and there are about 300 cases at U. S. Army General Hospital No. 2 at Fort McHenry, to which cases from these stations are immediately sent. There are also 1,900 cases at Camp Meade, although there have been but two deaths in all that number of cases, and an outbreak has been reported at Edgewood to the city health authorities, involving 1,100 soldiers and forty civilian employees. Notwithstanding the large number of cases, Dr. C. Hampson Jones, chief of the bureau of communicable diseases of the state board of health, stated that he did not consider the situation alarming. At this time the influenza does not appear to have spread generally throughout the state. Most of the reports received by the department of health have come from military camps, from Baltimore and Annapolis. There are about 500 cases in Annapolis.

MASSACHUSETTS

District Society Meeting.—The quarterly meeting of the Essex North District Medical Society was held at Amesbury Club, September 25. Lieut.-Col. Fred B. Lund, M. C., U. S. Army, Boston, read a paper on "The Present Needs of Our Country for Physicians," and Lieut.-Col. Channing Frothingham, Boston, M. C., U. S. Army, commanding the base hospital at Camp Devens, read a paper on "The Clinic Advantages of an Army Officer."

Personal—Dr. Llewellyn H. Rockwell, Boston, has been appointed resident physician at Long Island Hospital, succeeding Dr. Arthur L. Kinne.——Dr. John F. O'Brien, Taunton, has been appointed a trustee of the consumptives' hospital.——Dr. George McL. Waldie, for many years assistant physician at the State Infirmary, Tewkesbury, Mass., and later connected with the New Bedford Tuberculosis Sanatorium, has been appointed superintendent of the Fair Oaks Lodge Sanatorium, Wadena, Minn., and medical director of Sand Beach Sanatorium.——Dr. Arthur T. Schoomaker is under treatment in the Noble Hospital, Westfield, on account of tumors of the neck, and Dr. George V. Wager, Russell, is ill with pneumonia in the same institution.——Dr. Charles H. Winn, Roxbury, Boston, was appointed high medical examiner of the Massachusetts Catholic Order of Foresters, September 14, succeeding Dr. Francis J. Hanley, Whitman, resigned to acept a commission in the United States Service.——Dr. Arthur V. Pierce, New Bedford, has been commissioned First Lieutenant, M. C., Massachusetts State Guard, and has been assigned to the Seventh Infantry, succeeding Capt. Holder C. Kirby, New Bedford, resigned.

NEW YORK

Personal.—Dr. and Mrs. James H. Jackson, Danville, celebrated the fifty-fourth anniversary of their wedding, September 13.——Dr. Arthur D. Jaques, Lynbrook, has been appointed sanitary supervisor in Long Island, succeeding Dr. Overton.——Dr. Mary Walker, Bunker Hill, who has been seriously ill at the General Hospital, Fort Ontario, is convalescent.

Nurses Wanted.—The Womens' Chapter of the Division of the State Defense Council is cooperating with the State Hospital Commission in its effort to secure 1,000 nurses for the Hospital for the Dependent and Insane. The State Hospital Commission has a three-year course which leads to the registered nurse certificate, and a two-year course, candidates for which need only a grammar school education.

Health Commissioner Condemns Garbage Plant.—After a long and bitter fight waged for several years by the residents of Staten Island to force the Metropolitan By-Products Company to change its methods of handling garbage inasmuch as they constituted a public nuisance, Commissioner Copeland has given the company five days in which to abate the nuisance and unless it complies with this order or appeals to the health department for a modification of this ruling, the street cleaning department will be notified that no more garbage is to be taken to the plant for reduction. This plant has been the source of a very large part of the country's glycerin supply and it is probable that some less objectionable method of garbage reduction will be devised that will permit the company to continue to operate.

New York City

Personal.—Dr. Frank J. Monaghan, Brooklyn, has been appointed deputy commissioner and sanitary superintendent of the department of health, succeeding Dr. B. Franklin Knause, Brooklyn, resigned to accept a commission in the Army.

Work of Eye Clinics Curtailed.—The department of health is about to curtail its clinical work on the eyes of children to the extent of suspending the fitting of glasses. This step has been taken as a war measure and a policy to be pursued only for the period of the war. Clinics where the fitting of glasses has been the exclusive work in the past will be closed, but other eye clinics where diseases of the eye are treated will be continued.

The Influenza Epidemic.—The number of cases of influenza reported to the health department has increased day by day during the week of September 23. The largest number of cases thus far reported for one day was 324 new cases, September 27, this being double the number reported for the previous day. Although the health commissioner, Dr. Royal S. Copeland, asked the board of estimate for only $5,000 with which to combat the influenza epidemic, he was granted an appropriation of $25,000.

Borough Autonomy.—In October a radical change came in force in the administration of the health department. Health Commissioner Copeland has authorized the chief health officer in each borough to assume full responsibility and these officers will be known as assistant sanitary superintendents. This change is made in conformity with the charter requirements. The purpose is not to afford power in the part of the assistant sanitary superintendent, but to make clear the question of disciplinary authority.

OHIO

Convicted of Illegal Drug Sale.—Dr. Thomas E. Burgess, Toledo, is said to have been found guilty of the illegal sale of morphin by a jury in the probate court, September 13.

Reporting Venereal Disease.—According to a bulletin of the state department of health, Akron reports nearly 500 of the 2,000 cases of venereal disease reported to the registrar during August. This city has made the most complete report of any. It is believed that these diseases are not more prevalent in Akron than in Toledo, Cleveland and Cincinnati, larger cities, from which reports are very incomplete.

Physical Training Among Schoolchildren.—The *Ohio Public Health Journal* declares that 75 per cent. of the schoolchildren of Ohio have remediable physical defects. Only the larger cities of the state have such medical supervision in the schools as would improve the condition of most of these children. As shown by the Health and Old Age Insurance Commission of the state, there are 60,000 children in the rural schools who have very little physical supervision. About half of those in the city schools have some degree of supervision.

Personal.—Dr. Harley E. Ward and Cephas C. Greiner, both of Pemberville, sustained severe injuries by the overturning of their automobile while making a professional call near Pemberville, September 14.——An effort is being made to induce Dr. Augustus Ravogli to assume the professorship of dermatology in the medical department of the University of Cincinnati.——Dr. Frank H. Lamb, Cincinnati, who went to France last April under the auspices of the Child Welfare Bureau of the American Red Cross, will soon return to America to enter the Medical Reserve Corps.——Dr. William H. Peters has been appointed acting health officer of Cincinnati, pending the election of a successor to the late Dr. John H. Landis.

PENNSYLVANIA

Personal.—Dr. David Nathan, Norristown, has been commissioned a captain in the Canadian Army Medical Corps.——Dr. Edward H. Harris, Snow Shoe, is in the Bellefonte Hospital on account of chest injuries received in a recent automobile collision.

New State Dispensaries Open.—Five additional state dispensaries have been opened at York, Lancaster, Williamsport, Wilkes-Barre and Altoona, for the treatment of venereal diseases. The dispensaries are in connection with the state tuberculosis service, and the clinics are held in the same buildings.

Officers Elected.—At a recent meeting of the Union County Medical Society the following officers were elected: president, Dr. Harry R. Thornton, Lewisburg; vice president, Dr. Thomas C. Thornton, Lewisburg, and secretary-treasurer, Dr. Amos V. Persing, Allenwood.——At a recent meeting of the Lehigh Valley Medical Association the following officers were elected: president, Dr. Noah W. Reichard, Bangor; vice president, Dr. Frederick A. Fetherolf, Allentown; secretary, Dr. Alexander Armstrong, White Haven, and assistant secretary, Dr. Roger P. Batchelor, Palmerton.

State Medical Meeting.—The sixty-eighth annual session of the Medical Society of the State of Pennsylvania held in Philadelphia, September 23 to 27, had a smaller attendance than usual owing to the fact that many of its members are in the United States service. The officers elected for the ensuing year are as follows: president, Dr. Cyrus Lee Stevens, Athens; vice presidents, Dr. William Duffield Robinson, Philadelphia; Dr. John N. Sproul, Claysville; Dr. Julius H. Comroe, York, and Dr. Wesley Kunkle, Williamsport; secretary, Dr. Walter F. Donaldson, Pittsburgh; assistant secretary, Dr. Christian B. Longenecker, Philadelphia, and treasurer, Dr. George W. Wagoner, Johnstown. Harrisburg was chosen as the next place of meeting. Dr. Cyrus L. Stevens, the president-elect, has served the association for twenty-three years as its secretary and was voted a purse of $2,000.

Philadelphia

Personal.—Dr. Caroline M. Purnell has sailed for France as head of the second unit of the American Women's Hospitals.——Dr. Solomon Marks has been appointed assistant school medical inspector, health department, at a salary of $600.——Dr. Joseph M. Asher has been elected instructor in surgery at the Temple University.

Influenza Increases.—Two hundred new cases of "Spanish" influenza were reported to the bureau of health within twenty-four hours ending September 27. The records of the health department show that 123 of this number are civilians. The remaining seventy-seven are in the Fourth Naval District. Of the civilian cases, sixty-eight are in South Philadelphia, forty-six in North Philadelphia and nine in West Philadelphia.

VIRGINIA

Personal.—Drs. Frank G. Wilson, Norfolk, and James W. Reed, Ocean View, whose terms expired last month, have been requested by Dr. Ennion G. Williams, Richmond, secretary of the state board of health, to remain in office for the time being.——Dr. Roy K. Flannagan, chief of the Richmond Health Department, has declined the position of health officer of Hopewell.

Public Health Campaign.—An intensive health campaign was carried on in Gloucester County, September 20 to 28, under the auspices of the Virginia Anti-Tuberculosis Association and the state board of health. During the week leaders of the Virginia Anti-Tuberculosis Association will visit all the public schools in the county, and stimulate the interest of the public in behalf of the public health organizations.

New Clinics.—Dr. Powhatan S. Schenck, health commissioner of Norfolk, has requested that the venereal clinic conducted by the City Health Commission in conjunction with the federal authorities be provided with more adequate quarters.——The clinic for the treatment of the eye, ear, nose and throat was opened at Norfolk last month in charge of Dr. B. D. Downing. The hours for the clinic are from one to two o'clock, on Tuesday and Thursday afternoons.

Diploma and License Stolen.—Secretaries of state licensing boards and others interested, are requested to be on the lookout for a diploma from the Kentucky School of Medicine, Louisville, issued June 12, 1907, and a certificate from the Virginia State Board of Medical Examiners issued in June, 1915, both of which bore the name of Samuel L. Stallard. It appears that these papers were stolen while Dr. Samuel L. Stallard, Newport News, was on the train recently.

WEST VIRGINIA

In Memory of Dr. Megrail.—A special meeting of the Ohio county Medical Society was held in Wheeling, September 14, to adopt suitable resolutions of respect for the late Dr. William P. Megrail.

Personal.—Dr. Floyd F. Farnsworth, Frenchton, has resigned as a member of the state public health council and Dr. Herbert E. Sloan, Clarksburg, has been made his successor.——Dr. Vincent T. Churchman, Charleston, has been elected to succeed Dr. Farnsworth as president of the council. ——Dr. Walter Van Ness, in charge of the tuberculosis eradication department of the Bureau of Animal Industry, Washington, D. C., has located at Clarksburg, and will direct the work there.

Venereal Disease Campaign.—A bureau of venereal diseases has been established in the state in connection with the Public Health Council, and Dr. Floyd F. Farnsworth, Charleston, has been appointed acting assistant surgeon, U. S. P. H. S., and placed in charge of this bureau. The regulations of the Public Health Council include a declaration that venereal diseases are dangerous to the public health, the reporting of venereal diseases, instruction of patients, investigation of cases, protection of others from infection by venereally diseased persons, the prohibition of prescribing for venereal disease by druggists, the giving of certificates of freedom from venereal disease is prohibited, and it is declared that all records concerning persons infected with venereal disease should be inaccessible to the public except in so far as publicity may attend the performance of the duties in accordance with the regulations and laws of the state.

CANADA

Most Ontario Doctors Observe Temperance Act.—According to the returns for the mouth of August, about 10 per cent. of the doctors of Ontario are issuing most of the prescriptions for liquor in that province. One doctor in Hamilton is said to have issued 725 in the month. Six issued an average of 456. Ninety per cent. of the doctors of the province issued an average of 5.6.

Personal.—Dr. Frederick N. G. Starr, Toronto, has been appointed consulting surgeon with the British forces in France, and has reached there in safety.——Col. Murray MacLaren, C.M.G., St. John, N. B., who has been overseas some years, has been appointed commanding officer of Granville Hospital, Buxton, England.——Lieut. Henry C. Pearson, Toronto, has returned on three months' leave. He enlisted the first month of the war and has been serving in France for the past three years.——Lieut.-Col. Charles S. McVicar, Toronto, was recently recalled for duty in Canada and has arrived home. He was one of the six members of the University of Toronto Base Hospital mentioned in dispatches when it was at Saloniki.——The following lieutenants in the medical service will go from the Third Military District, Kingston, Ont., with the Siberian contingent: Hendry Connell, J. H. Munroe, J. A. Lalonde, S. J. R. Horne, J. Sharp and F. S. Tisborne.

GENERAL

Prevention of Infant Mortality.—The ninth annual meeting of the American Association for the Study and Prevention of Infant Mortality will be held at Asheville, N. C., November 12 to 14. The program pays especial attention to war subjects.

Industrial Medicine.—At the meeting of the Seventh Annual Safety Congress in St. Louis, September 20, Dr. Clarence D. Selby, U. S. P. H. S., discussed industrial medicine as an increased production in war times, and urged increasing cooperation by employers, employees, medical schools, and the medical profession generally.

Railroad Relief Committee Appointed.—Director-General McAdoo has announced the appointment of the following committee on health and medical relief for the railroad administration: Dr. J. E. Dunott, chairman, and Drs. George W. Cale, Jr., St. Louis; Victor G. Heiser, New York City; Thomas R. Crowder, Chicago, and Henry M. Bracken, St. Paul. The committee is charged with recommending all necessary measures to protect the health of employees of the railroads under federal control, based on a survey of conditions.

Leprosy Expert Dies.—Moses Tran Clegg, superintendent of the Queen's Hospital, Honolulu, noted as a bacteriologist and especially for his research work in leprosy, died in Honolulu, August 14. Mr. Clegg was the assistant director of the Bureau of Sciences of the Philippines in 1908, and a year later succeeded in isolating and propagating the leprosy bacillus. He also spent considerable time in work on bubonic plague in San Francisco and New Orleans, and served for eighteen months as laboratory director in the port of New York in the United States Public Health Service.

Influenza.—Influenza, up to September 26, had been reported to the Public Health Service in twenty-six states. It continues to spread rapidly and probably cases will be found in all of the states. September 25, there were 5,000 new cases reported in the Army camps, with 155 deaths. The total cases in the camps to that date were about 30,000. It is believed, however, that as far as the Army camps are concerned, the situation is under control, and in some camps the disease is distinctly on the wane. At the Great Lakes station, near Chicago, among the 45,000 men in camp there had been about 500 deaths from influenza and pneumonia since the beginning of the epidemic, September 9. The disease first appeared in Illinois at Great Lakes, September 9, and since that date there had been about 9,000 cases in the camp.

The Chemical Convention.—The National Exposition of Chemical Industries, held in New York City during the week of September 23, was the most successful ever held in this country, owing to the many developments and advances in chemical science during the war period. One of the most interesting addresses from the medical standpoint was that of Dr. Charles H. Herty in which he suggested a plan for the establishment of a national research laboratory for chemists similar to that of the Rockefeller Institute for Medical Research and providing facilities for experimental work in the chemistry of medicine. This suggestion proposes an institution in which adequate provision would be made for laboratory tests of all kinds, and through which cooperation should be established with the organic laboratories of universities and with the hospitals of the country.

FOREIGN

The Golgi Scholarship.—In honor of Professor Golgi, senator, who retires this year from the chair of pathology and histology at the University of Pavia, it is proposed to found a scholarship in the medical department for the orphan of some physician, preferably one whose father was lost during the present war. Contributions may be sent to the treasurer, Tesoriere dell' Ordine dei Medici della Provincia di Pavia.

Welfare Work for the Young.—An exchange quotes the *Münchener medizinische Wochenschrift* to the effect that the Prussian authorities have decreed that every city and rural district is to organize an official board for welfare work for the young. The board is to comprise the governor or mayor, the district physician, some members of the clergy, and twelve experienced men and women, including some medical men or women. They are to have oversight of orphans, illegitimate children, the aid for indigent minors, etc.

Medical School for French West Africa.—According to a report of U. S. Consul W. J. Yerby at Dakar, Senegal, the French government has authorized the establishment of a medical school at Dakar, which was to be opened, Oct. 1, 1918. The school will be under the direct authority of the governor general of French West Africa and under the technical control of the inspector-general of the health medical services of that colony. The object in establishing the school is to supply the needs of the country, especially on account of the war, as thousands will return from the battlefields wounded and in bad health, requiring special medical treatment.

Influenza in Europe.—The epidemic of "Spanish influenza" seems to have been mild in Italy. The cases among the troops on active service have been few and mild. In Switzerland the disease was unusually severe and pneumonia was frequent. Several deaths among physicians were mentioned. One Swiss physician states that in his fifty-three fatal cases, forty-one of the patients were between 15 and 30 and nearly all absolutely healthy young people. This same prevalence of the severer cases among the young is mentioned in the reports from Germany cited in the *Hospitalstidende* of Copenhagen. The fatality is said to be highest between 20 and 40. Besides pneumonia and empyema, serous meningitis, sinusitis and otitis media were observed, but infants seemed to escape entirely. This was noticed also in Spain, infants showing no trace of the disease when both parents and the nurse had it. Even Pfeiffer, the discoverer of the influenza bacillus, was not certain whether the bacteriologic findings were positive for this bacillus, and others in Germany, Sweden and Norway were also dubious about their findings. Lubarsch found pseudomembranes in the throat in some cases. In the Netherlands, in a certain proportion of the cases, diarrhea and abdominal pains were the predominant symptoms. A writer in the *Nederlandsch Tijdschrift* remarks that after this no one can refer to influenza as a "harmless disease." The cry comes also from Portugal that "grippe kills with its pneumonia."

SOUTH AND CENTRAL AMERICA, MEXICO AND WEST INDIES

Brazilian Medical Mission in France.—An exchange states that the Brazilian minister announces that Brazil is sending a medical mission to France. The party is to consist of fifty doctors besides a number of students. They are to be attached to the Brazilian Hospital already installed near the front.

Home for Medical Society at Rio de Janeiro.—With appropriate ceremony the cornerstone was laid recently for the building destined to be the home of the Sociedad de Medicina e Cirurgia of Rio de Janeiro. The president of the society, Dr. O. de Oliveira, is said to have been chiefly responsible for this realization of the long cherished dream of the members. The society was founded thirty-three years ago, and it has its own museum and library. The funds for the construction of the building, it is said, have all been subscribed, the national authorities having presented the society with the site, and the municipality having appropriated 6 *contos* for the purpose. The society and its friends in medical and pharmacist circles have raised the balance needed.

CORRECTION

Director Base Hospital No. 53.—The adjutant of Base Hospital No. 53 in France informs us that Lieut.-Col. Daniel A. Sinclair, M. C., U. S. Army, assumed command of this hospital at Camp Hancock, Ga., on May, 1918, and has been in command continuously since that date. The item in The Journal of July 20, 1918, stating that Lieut.-Col. Albert E. Halstead, M. C., U. S. Army, had been placed in charge of this hospital is incorrect.

PARIS LETTER

Paris, Sept. 5, 1918.

The American Crusade Against Tuberculosis

In a previous letter (The Journal, June 8, 1918, p. 1784), mention was made of the crusade begun in France against tuberculosis by the Rockefeller Foundation under the direction of Dr. Livingston Farrand, president of the University of Colorado. Work was begun in one of the densely populated arrondissements or districts of Paris, the nineteenth, and in the département d'Eure-et-Loir. A dispensary system was established, with visiting nurses, and an ingenious method of popular education was inaugurated by means of demonstrative conferences, striking posters, and amusing as well as persuasive pamphlets. The département d'Eure-et-Loir has been traversed effectively during the past two or three months by a dispensary autotruck, provided with everything needed to teach the public and to carry conviction to them (cinematography, etc.). The same outfit has also been taken through the départements of Loir-et-Cher, Indre-et-Loir, and Cher, and is at present covering the département de l'Allier. Another outfit after being taken through the départements d'Ille-et-Vilaine and du Finistère, is now covering the département des Côtes-du-Nord. These educational and prophylactic tours have met with great success, more than half of the population having participated in the conferences.

Physics, Chemistry and Biology as Required Premedical Studies

In France, before entering on medical studies proper, one year is spent in the Facultés des sciences in the study of physics, chemistry and natural sciences—called familiarly the P. C. N. The value of this premedical work as now organized is questionable. These courses are not intended for future medical students alone; hence it is not right to impose this premedical requirement on them. Without a doubt these subjects are indispensable to physicians, but some people contend that it would be better to revert to the system which was in vogue twenty-five years ago under which one year was devoted to the study of physics, chemistry and biology taught in the medical department by physicians, who emphasized particularly the medical application of these sciences.

A Flying Operating Unit

At a recent meeting of the Académie de médecine, Dr. Walther presented the plans and photographs of a surgical avion designed by M. Nemirowski and Dr. Tilmant as capable of rendering service to the severely wounded on the battlefield itself. This avion, the idea for which was encouraged by the late Professor Pozzi, can transport its load anywhere. It is designed to carry a complete surgical equipment—personnel of three—a complete roentgenographic outfit, sterilized instruments, gowns, dressings, in fact everything needed to perform eight emergency operations. The entire outfit, including an autoclave, a reservoir of sterilized water, accumulators and steam sterilizer, weighs only 360 kilograms and occupies a very limited space. The first avion is ready for service. On the initiative of Dr. Stepinski, director of the Polish Service de Santé, a committee has been formed which will present a group of complete surgical avions of this kind to the French army. It will be known as the "escadrille Pozzi" in honor of the man who encouraged the initiative of its inventors.

Antigas Measures

At a conference held recently at l'Ecole d'application de médecine et de pharmacie militaires du Val-de-Grâce, consideration was given the properties of the gases now used by the enemy, protective measures against these gases, and the best means for disseminating such knowledge to the physicians now in service. This conference was attended by the medical directors of the Services de Santé of the army, the chiefs of the medicolegal and hygienic centers of the zone of the interior, the chiefs of special services, etc.

The American Red Cross at Lyons

M. Edouard Herriot, mayor of Lyons, gave a dinner in honor of the commandant Marshall Hale, appointed director of the southern intermediate zone of the American Red Cross, of which Lyons is headquarters. The notables of the region were present at this dinner, also the United States consul. Marshall Hale stated that it was his intention to make Lyons a center of large activities, aiding in the most extensive way the numerous institutions and agencies now in operation. In the name of Lyons and the region, the mayor expressed his liveliest thanks to the speaker.

The Vacation Colonies

The Oeuvre des *colonies* de vacances was founded in 1882 by Mme. Edmond de Pressensé *for the purpose* of removing poor children from the *pernicious surroundings* of the large ities and giving them an *opportunity to benefit* from the lean, healthy atmosphere of the country, the mountains and he sea, strengthening them physically as well as *morally* (The Journal, Nov. 12, 1910, p. 1745). Since the beginning of the war, 22,000 children of *both* sexes, from 5 to 14 years of age, *orphans*, *children* of refugees or of men in the service, have benefited from this *movement*.

Japanese Red Cross Mission in France

The *Japanese* Red *Cross* has sent a commission to France to study the French Service de Santé and to convey to the French aid societies (*sociétés de secours*) the good wishes of our ally of the extreme Orient. This mission visited the principal formations of the Red Cross societies in Paris and then left for the front.

Red Cross Postage Stamps

According to the terms of an agreement with the "*administration des postes*" (postal authorities) of Belgium, England, Italy and Serbia, it has been decided that the stamps used in France for the benefit of the Red Cross may also be used for postage stamps on *mail whose destination* is the countries mentioned. Likewise, the Red Cross special postal stamps issued in *these* countries *will* be accepted as franking mail destined for France.

The War Blinded

A group of *aveugles de guerre* (war blinded) has issued *a call to all* soldiers who have sustained eye wounds, inviting them, as other classes of the maimed have *done*, to organize *and* found *syndicats professionnels* whose object will be to establish and maintain uniformity and cooperation between all the various agencies looking after the war blind and the schools engaged in their reeducation. Such an organization *would be able to* purchase raw materials at lower *prices, and* would also reduce the selling expense considerably.

Gift of Cuban Physicians to the War Medical Aid Fund

Prof. José A. Presno of Havana, Cuba, has sent to the Association des médecins de France, for its fund for *assistance confraternelle de guerre*, 7,000 francs contributed by physicians of Cuba, with a message stating that they wish to "reaffirm their admiration of the glorious Latin nation and their gratitude to French medical science, the most faithful guide and the best inspiration of all medical culture."

LONDON LETTER

London, *Sept. 3, 1918.*

Medical Students and the War

The effect of the war on the number of medical students has been described from time to time in previous letters. The approaching opening of a new medical session affords the opportunity of reviewing the present position. Before the war, in the years 1910-1914, the average annual entry of first year medical students was about 1,440. During the war the number of entries has been increased to about 2,000. Thus the number of students pursuing their curriculum in the medical schools has steadily increased. In May, 1916, the total was 6,103; in January, 1917, 6,682; in October, 1917, 7,048, and in May, 1918, 7,630. Notwithstanding this increase, the great withdrawal of students from the medical schools for combatant service or for service as surgeon probationer in the navy has resulted in a considerable deficiency in fourth and fifth year students, who can furnish only about three fourths of the yearly entry into the profession considered desirable to make up for the wastage. The numbers of medical students now studying are, for the various years: first year, 1,378; second year, 1,249; third year, *1,050*; fourth *year*, 759; fifth year, 944. In 1920, when the present *fourth year* *students are* due to qualify, the *deficiency of entries* into the profession will be at its *maximum*. *Another effect* of the war is a great increase in the number of women students. Their percentage *of* the total is: first year, 32; second year, 33; *third year, 32*; fourth year, 27; fifth year, 18. Thus, although *the percentage* of women has remained almost constant *during* the four war years, it shows a considerable *increase on* the prewar figure, which corresponds to the fifth year students. The total number of physicians on the register is 43,819, which is thus distributed in the United Kingdom: England, 54 per cent.; Scotland, 32 *per* cent.; Ireland, 14 per cent. Urgent *representations* have been made to the government as to the threatened shortage of physicians due to the withdrawal of students for *combatant* service, a number of third year students have been allowed to return from active service to complete their studies, and students on their way to qualification, *liable to be called* to the colors, are being allowed to complete *their studies*. The minister of national service has undertaken to *provide* that if possible the number of students in *training shall* be *kept* at a level sufficient to give an annual yield of 1,000.

Tetanus Following the Subcutaneous Injection of Gelatin

The subcutaneous *injection* of gelatin is supposed to *increase* the coagulation of the blood and therefore has been used as a hemostatic and also to promote coagulation in aneurysms. For the latter *object* it was introduced in 1898 *by two French* workers, Lancereaux and Paulesco. But gelatin *sometimes* contains the spores of tetanus bacilli, *and* cases of tetanus have followed its subcutaneous *injection*. A case that occurred in a London hospital has just been the subject of a coroner's inquest. A *man*, aged 25, supposed *to be suffering* from typhoid fever, had severe intestinal hemorrhage for which 20 c.c. of gelatin (guaranteed to be sterilized *for subcutaneous use*) was injected into the left thigh. Five days *later* he began *to complain* of inability to open his *mouth properly*, and stiffness and pain in the muscles *of* the back *of the neck and trunk.* A typical attack of tetanus developed and proved *fatal* on the following *day*. The *spasms* notably affected the left thigh. The *necropsy revealed intestinal typhoid* ulcers, *and* a *small* abscess in the thigh, apparently at the site of *the injection*. *From this Dr.* Spilsbury, [illegible] expert, who made the necropsy, obtained [illegible] those of tetanus. A verdict of death by misadventure due to tetanus was returned. Dr. Parkes Weber, under whose care the patient was, suggests the possibility that the bacilli might not have *come from the gelatin but* from an imperfectly sterilized *syringe or by way of the ulcers* from ingested food.

Marriages

Lieut. James Edward McDowell, M. C., U. S. Army, Philadelphia, on duty with the American Expeditionary Forces in France, to Miss Lillian Dauphney of Montreal, in London, June 18.

Lieut. James Eddy Arnold, M. C., U. S. Army, Miles City, Mont., to Miss Laina Louisina Laury of Louisville, Ky., September 7.

Capt. Oliver Linwood Stringfield, Jr., M. C., U. S. Army, Marshall, N. C., to Miss Lois Wood of New Canaan, Conn., August 28.

Lieut. Samuel Wilson McEwan, U. S. N. R. F., Cincinnati, to Miss Ethel Belle Allee, also of Cincinnati, September 11.

Clarence Albert Butler, Dell Rapids, S. D., to Miss Daisy Dean Carr of Marison, S. D., at Soiux Falls, S. D., July 11.

Lieut. Clayton Willard Eley, U. S. Navy, Detroit, to Miss Katie Brinkley of Suffolk, Va., September 11.

Frank Oscar Burk to Mrs. Anne Applegren, both of Davenport, Iowa, at Galesburg, Ill., September 6.

Josiah Shaftesbury Davies, Tacoma, Wash., to Miss Ruth E. Irle, at Jacksonville, Ore., September 11.

Thomas B. Horton, Curtis Bay, Md., to Mrs. Grace H. Norwood of Baltimore, September 21.

Irwin Wilson Voorhees to Miss Hazel Letitia Coleman, both of New York City, September 7.

John Joseph Burke to Miss Catherine F. Lynd, both of Schenectady, N. Y., September 14.

Grace Lynde Meigs, Washington, D. C., to Thomas Crowder, at Keokuk, Iowa, recently.

Walter J. Pellett, Manitowoc, Wis., to Miss Ellen Kikulski of Chicago, August 7.

Julian Herman Lewis to Miss Eva Overton, both of Chicago, September 4.

Eugene C. Hamley to Mrs. Alice Dyer, both of Pasco, Wash., in August.

Fraray Hale, Bridgeport, Conn., to Mrs. Mabel Camp Dorsey, recently.

Deaths

Col. Joseph Basil Girard, M. C., U. S. Army (retired), San Antonio, Texas; University of Michigan, Ann Arbor, 1867; aged 71; a Fellow of the American Medical Association, and a member of the Association of Military Surgeons of the United States; who entered the United States service as assistant surgeon in 1867; major and surgeon in 1888, lieutenant-colonel and deputy surgeon-general in 1901, and colonel and assistant surgeon-general in 1902; retired in 1910, on attaining the age of 64 years; was with General Crook in the Apache Campaign in 1873, and for nine years saw almost continuous service in Indian warfare; died at his home, August 25.

Major Walter Whitney, M. R. C., U. S. Army, Augusta, Ga.; Columbian College, Washington, D. C., 1872; aged 69; at one time a Fellow of the American Medical Association; a member of the Association of Military Surgeon of the United States; acting assistant surgeon, U. S. Army, from 1880 to 1890, and from 1898 to 1901, during which time he served in Indian campaigns in Arizona and New Mexico, and later in the Philippine Islands; prior to his Army service, Indian agency physician from 1875 to 1879, and from 1893 to 1896 an officer of the U. S. P. H. and M.-H. Service; since 1913 on duty at the Augusta Arsenal, Augusta, Ga.; died in that place, September 4, from heart disease.

Charles Barnsdall Parker, Cleveland; University of Wooster, Cleveland, 1877; M.R.C.S. (Eng.), 1880; aged 65; a Fellow of the American Medical Association; one of the founders of the Cleveland General, and St. Luke's hospitals, and visiting surgeon to St. John's Hospital; dean and professor of clinical surgery in Ohio Wesleyan University Medical School, Cleveland, from 1894 to 1898, and thereafter senior professor of clinical surgery in Western Reserve University, Cleveland; local surgeon of the Lake Shore and Michigan Southern Railroad; died at his summer home on Wooster Road, Rocky River, September 18, from heart disease.

Capt. William Burrows Hudson, M. R. C., U. S. Army, Washington, D. C.; George Washington University, Washington, D. C., 1905; aged 40; a Fellow of the American Medical Associaton; formerly major, M. C., N. G. D. C.; who went overseas in the autumn of 1917, in command of an ambulance company of the National Guard of the District of Columbia, incorporated in the Rainbow Division; while caring for the wounded on the western front in France, was instantly killed, August 1, by the explosion of a shell.

Edgar Miller Holmes, Boston; Harvard Medical School, 1895; aged 50; a Fellow of the American Medical Association; associate professor of otology and laryngology in Tuft's College Medical School, Boston; aural surgeon in the Boston City Hospital and Boston Dispensary; consulting aural surgeon to the Massachusetts Infants' Asylum; and ear, nose and throat surgeon at St. Elizabeth's Hospital; was drowned by the overturning of his canoe at Point Allerton, Mass., September 19.

Emerson K. Kellenberger, Yates Center, Kan.; Medical College of Ohio, Cincinnati, 1871; aged 68; a Fellow of the American Medical Association and president of the Woodson County Medical Society in 1914; for twenty years local surgeon of the Missouri Pacific Railway Company; for two years coroner of Franklin County, Kan., and secretary of the first board of medical examiners of his judicial district in Arkansas; died at his home, September 11, from cerebral hemorrhage.

William Pickard Megrail, Wheeling, W. Va.; Western Reserve University, Cleveland, 1888; aged 59; a Fellow of the American Medical Association; a specialist in obstetrics and diseases of children; local surgeon for the Baltimore and Ohio System, and the Wheeling Traction Company; a member for several years and president of the first branch of the Wheeling City Council; died at his home, September 30, from cerebral hemorrhage.

Charles Henry Norred, Minneapolis, Minn.; Jefferson Medical College, 1886; aged 76; a veteran of the Civil War, in which he served as surgeon in the Seventh Illinois Volunteer Cavalry; formerly medical director for the department of Minnesota of the Grand Army of the Republic; surgeon to the Soldiers' Home; died at the Battle Mountain Sanatorium, Hot Springs, S. D., September 16.

Robert Edward McCullough, Flint, Mich.; Starling Medical College, Columbus, Ohio, 1898; aged 50; a Fellow of the American Medical Association; while driving his motor car over a grade crossing over the Corunna Road, near Lansing, Mich., August 28, was struck by a passenger train and received injuries which caused his death a few minutes later.

Robert Jarvis Mitchell, Girard, Ill.; Rush Medical College, 1871; aged 74; a Fellow of the American Medical Association, and a charter member of the Macoupin County Medical Society, of which he was once president; for ten years president of the Girard board of education; died at his home, September 8.

Alfred Mahlon Bigelow, Mansfield, Mass.; Boston University School of Medicine, 1900; aged 55; also a graduate of Harvard Veterinary College; at one time town physician of Mansfield; died in the Massachusetts General Hospital, Boston, from adenocarcinoma of the sigmoid, July 30.

James E. T. Holiman, Little Rock, Ark.; College of Physicians and Surgeons, Little Rock, 1907; aged 51; a member of the Arkansas Medical Society; associate professor of theory and practice of medicine in his alma mater; died at his home, September 17, from cerebral hemorrhage.

John H. Demarest, White Plains, N. Y.; New York Homeopathic Medical College, New York City, 1865; aged 81; for thirty years a member of the staff of the Metropolitan Hospital, Blackwell's Island, and at one time president of the medical board; died at his home, September 14.

Lieut. Gordon Trevor Courtenay, U. S. N., San Diego, Calif.; Northwestern University Medical School, Chicago, 1908; aged 31; a Fellow of the American Medical Association; died in the New York Naval Hospital, September 23, from pneumonia following influenza.

Jacob Samuel Price, Beaumont, Texas; Tulane University, New Orleans, 1891; aged 53; a member of the State Medical Association of Texas; at one time a member of the state board of health; died in the Hotel Dieu, Beaumont, September 12, from heart disease.

Samuel Allan Lacock, Canonsburg, Pa.; Jefferson Medical College, 1877; aged 69; a member of the Medical Society of the State of Pennsylvania; postmaster and once burgess of Canonsburg; died in the West Penn Hospital, Pittsburgh, September 18.

Ralph Emerson Stevens, Marlboro, Mass.; Harvard Medical School, 1897; a member of the Massachusetts Medical Society; aged 48; for fifteen years chairman of the local board of health; died at his home, September 18, from uremia.

Julius Edward Block, Rembrandt, Iowa; Detroit College of Medicine and Surgery, 1904; aged 38; was found dead in his office, September 3. The coroner's verdict was that he died about August 28, from an overdose of intoxicants.

James Wallace Ford, Jr., Mount Carmel, Pa.; Hahnemann Medical College, Philadelphia, 1905; aged 37; a member of the Medical Society of the State of Pennsylvania; died in his office, September 17, from acute dilatation of the heart.

Albert Marvin Hutton, Kalamazoo, Mich.; Detroit Homeopathic Hospital, Detroit, 1905; aged 45; at one time a Fellow of the American Medical Association; died at the Fairmount Hospital, Kalamazoo, August 8, from diabetes.

Ross B. Rowe, Reading, Pa.; University of Pennsylvania, Philadelphia, 1885; aged 57; a member and once vice president of the staff of St. Joseph's Hospital, Reading; died at his home, September 20.

Mott Dwight Cannon, New York and Greenwich, Conn.; New York Homeopathic Medical College, New York City, 1882; aged 59; died suddenly at Poultney, Vt., September 21.

George Volney Bush, Dawson, Ala.; Southern Medical College, Atlanta, Ga., 1890; aged 49; died in Chattanooga, Tenn., August 18, a day after an operation for cholelithiasis.

Charles E. Smith, Colorado Springs, Colo.; Louisville (Ky.) Medical College, 1878; aged 63; also a druggist; died at his home, September 6.

Joseph T. Bright, Covington, Ky.; University of Pennsylvania, Philadelphia, 1866; aged 76; died at his home, September 3.

Francis A. Woodward, Springfield, Tenn.; University of Louisville, Ky., 1882; aged 60; died at his home, September 18.

John Barton Sanders, LaGrange, Ga.; a nongraduate practitioner since 1888; aged 55; died at his home, September 15.

Zachariah C. Myers, York, Pa.; University of Maryland, Baltimore, 1881; aged 59; died at his home, September 9.

The Propaganda for Reform

In This Department Appear Reports of the Council on Pharmacy and Chemistry and of the Association Laboratory, Together with Other Matter Tending to Aid Intelligent Prescribing and to Oppose Medical Fraud on the Public and on the Profession

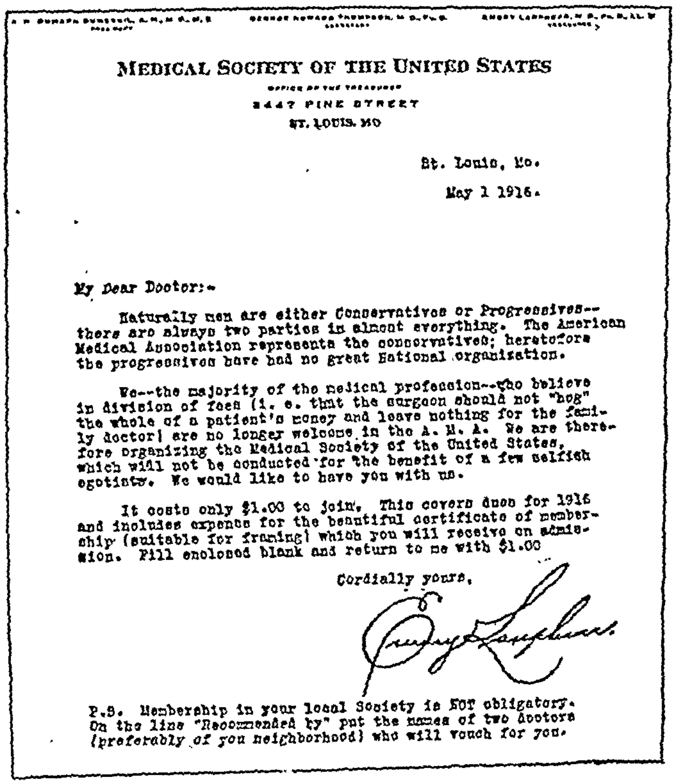
MEDICAL SOCIETY OF THE UNITED STATES

From "Division of Fees" to "Down With Autocracy"

The "Medical Society of the United States" has for its "Honorary President" one A. H. Ohmann-Dumesnil, A.M., M.D., M.E., Sc.D., Ph.D., and for its "Secretary and Treasurer" one Emory Lanphear, M.D., C.M., Ph.D., LL.D. As originally planned, the "society" *seems* to have been based on the idea of organizing the "fee-splitters." In May, 1916, the birth of the organization was announced to the medical profession through a letter signed Emory Lanphear, written on the stationery of the "Medical Society of the United States." Even in its embryonic state the society had A. H. Ohmann-Dumesnil, A.M., M.D., M.E., for its president, and Emory Lanphear, M.D., Ph.D., LL.D., as its treasurer. The letter read in part:

> "We—the majority of the medical profession—who believe in division of fees (i. e., that the surgeon should not 'hog' the whole of a patient's money and leave nothing for the family doctor), are no longer welcome in the A. M. A. We are therefore organizing the Medical Society of the United States, which will not be conducted for the benefit of a few selfish egotists. We would like to have you with us.
>
> "It costs only $1.00 to join. This covers dues for 1916, and includes expense for the beautiful certificate of membership (suitable for framing), which you will receive on admission. Fill enclosed blank and return to me with $1.00."

But presumably the idea of organizing on a basis of "fee splitting" did not make a hit, so the lure was changed. Today physicians are approached with the plea that the "Medical Society of the United States" will make the medical world free for democracy; it is, we are assured, a "Society of Protest Against the Autocracy of the A. M. A.," and a "Society of Medical Democracy."



MEDICAL SOCIETY OF THE UNITED STATES
3447 PINE STREET
ST. LOUIS, MO

St. Louis, Mo.
May 1 1916.

My Dear Doctor:-

Naturally men are either Conservatives or Progressives--there are always two parties in almost everything. The American Medical Association represents the conservatives; heretofore the progressives have had no great National organization.

We--the majority of the medical profession--who believe in division of fees (i. e. that the surgeon should not "hog" the whole of a patient's money and leave nothing for the family doctor) are no longer welcome in the A. M. A. We are therefore organizing the Medical Society of the United States, which will not be conducted for the benefit of a few selfish egotists. We would like to have you with us.

It costs only $1.00 to join. This covers dues for 1916 and includes expense for the beautiful certificate of membership (suitable for framing) which you will receive on admission. Fill enclosed blank and return to me with $1.00

Cordially yours,
Emory Lanphear

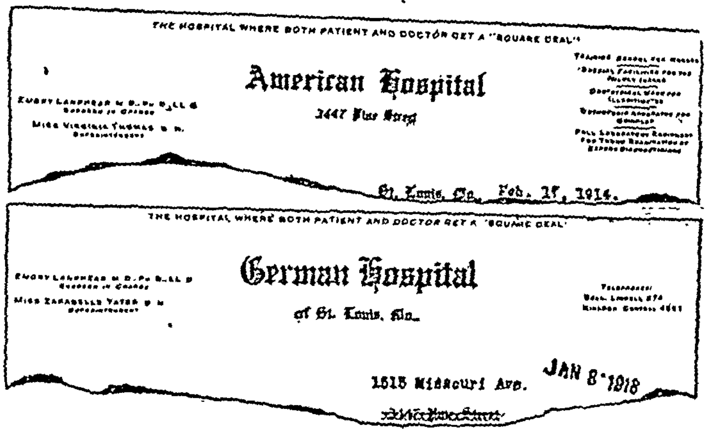
P.S. Membership in your local Society is NOT obligatory. On the line "Recommended by" put the names of two doctors (preferably of you neighborhood) who will vouch for you.

The "Medical Society of the United States," was originally organized on a basis of "fee-splitting," as is shown by the reduced facsimile of a letter sent broadcast in 1916, announcing the birth of the new "society." Apparently, "fee-splitting" as a rallying point did not bring in the desired returns, so today the "Medical Society of the United States" is alleged to be a "Society of Protest Against the Autocracy of the A. M. A."

Membership costs "only $1.00 . . . including the cost of a beautiful certificate of *membership*." No penalties or punishments are involved for belonging to other societies, and:

> "Joining our body *need not* affect your membership *in any* other society—even the A. M. A., if you wish to belong to it, and be 'bossed' by the 'Simmons Gang'."

The dollar for the "beautiful certificate" and membership is solicited by means of circular letters signed "Emory Lanphear," coming from 3447 Pine St., St. Louis, Mo., the address of what has been variously called the "American Polyclinic," the "American Hospital," and later, the "German Hospital." The "Surgeon-in-Charge" of the "German Hospital" is Emory Lanphear, M.D., C.M., Ph.D., LL.D. When running under the name of the "*American Hospital*," Lanphear solicited operative work on a "division of fees" basis, which, the general practitioner was told, meant that "you are to have 40 per cent. of all fees received from your patients sent to our staff for operation or treatment."



THE HOSPITAL WHERE BOTH PATIENT AND DOCTOR GET A "SQUARE DEAL"
American Hospital
3447 Pine Street
St. Louis, Mo. Feb. 27, 1914.

THE HOSPITAL WHERE BOTH PATIENT AND DOCTOR GET A "SQUARE DEAL"
German Hospital
of St. Louis, Mo.
1515 Missouri Ave. JAN 8 1918

Reduced facsimile of the letter-heads of an institution known variously as the "*American Hospital*" and the "German Hospital." The change in name from "American" to "German" seems to have taken place early in 1915—when things German *were more popular* and profitable than they are today!

With the change in name from "American Hospital," to "German Hospital," Lanphear appealed for a "portion of your operative work on a basis of pure reciprocity." This "pure reciprocity" seems to have been a still more liberal distribution of the patient's money, for from a 40 per cent. basis it was raised to an even fifty-fifty. Said Lanphear, in a letter sent out a few months ago:

> "*I wish also to inform you in spite of the despicable opposition of the hypocritical gang in charge of the A. M. A., and the no less contemptible action of the St. Louis Medical Society, I am going to remain in St. Louis and continue to do surgical work upon a 'division of fee' basis. To be more explicit, if you bring me a case for operation I shall allow you one half of the fee for your time, trouble, responsibility and help in the management of the case.*"

Before leaving the interesting professional personality of Lanphear, and carefully avoiding any details of a personal nature, we may remind our readers that as long ago as 1908 Lanphear was the "Dean" of the "Hippocratean College of Medicine," with A. H. Ohmann-Dumesnil, A.M., M.D., M.E., Sc.D., "Vice-Dean." At that time Lanphear sent out letters to physicians proposing the organization of a "Post Graduate Faculty" on the following basis:

> "Those who hold full professorships shall purchase stock in the corporation to the amount of $1,000.00; those who become lecturers or instructors shall pay in the sum of $500.00; those who are to be merely clinical assistants will buy ten shares of stock, $100.00."

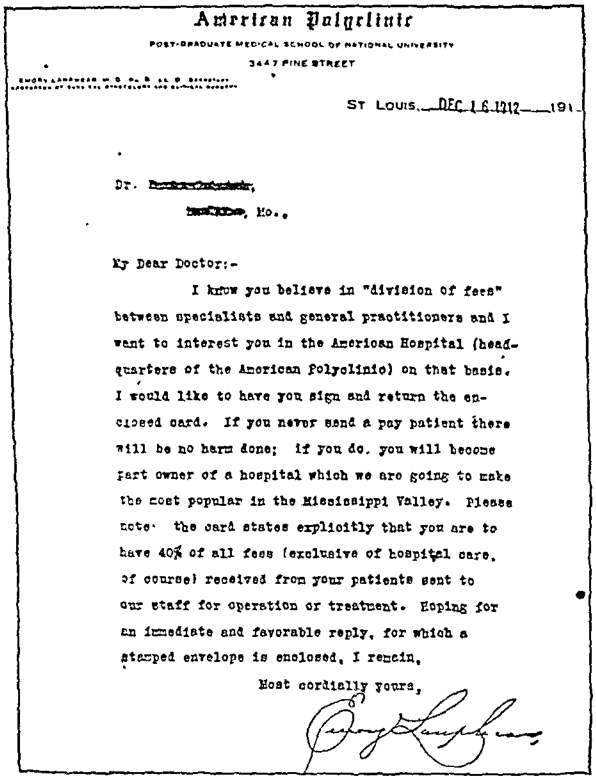
The "Hippocratean College" was a "sundown" affair; it never graduated a student, and expired in 1910.

But to come back to the "Society of Medical Democracy": the "Medical Society of the United States" seems to have been born in 1916. Its parents, so far as is apparent, seem to have been Lanphear and Ohmann-Dumesnil. The latter, it may be remembered, used to be the editor and proprietor of the *St. Louis Medical and Surgical Journal*, a publication so obviously venal, that its value to the nostrum makers, whose interests it espoused, must have been small. Advertising pages, "original articles" and "editorials"—all were used to puff nostrums of the crudest type. It was Ohmann-

Dumesnil and his journal that came to the defense of the "patent medicine" interests when they were so hard hit by Mr. Adams's "Great American Fraud" series. In commenting on this phase of "patent medicine" activities, *Collier's*, in January, 1907, said:

> "Headache powders came in for a considerable share of attention in the patent medicine articles. There was much talk of libels among the headache powder makers, but they decided upon the safer methods of hiring a meretricious medical publication, the *St. Louis Medical and Surgical Journal*, to print an article in which the *Collier's* statements were branded as lies, and the *Collier's* editors and writers as liars and libelers. This article the Proprietary Association of America circulated in pamphlet form. The journal which printed it died a natural death a few weeks later. Its editor, one O. H. Ohmann-Dumesnil, has just appeared in the public prints in an unsavory connection with a corrupt lobbying project in St. Louis."

Some of the nostrums that Ohmann-Dumesnil has recommended are: "Sanmetto," "Gonosan," "Cactina Pillets," "Pepto-Mangan," "Satyria," "Campho-Phenique," "Tongaline," "Germiletum," "Narkogen," "Nosophen," "Mercauro," "Arsenauro," and "Hydrozone." Many of these testimonials were, of course, used by the manufacturers in their advertising "literature."



American Polyclinic

POST-GRADUATE MEDICAL SCHOOL OF NATIONAL UNIVERSITY

3447 PINE STREET

ST LOUIS, DEC 16 1912 191

Dr. [redacted],

[redacted], Mo.,

My Dear Doctor:-

I know you believe in "division of fees" between specialists and general practitioners and I want to interest you in the American Hospital (headquarters of the American Polyclinic) on that basis. I would like to have you sign and return the enclosed card. If you never send a pay patient there will be no harm done; if you do, you will become part owner of a hospital which we are going to make the most popular in the Mississippi Valley. Please note: the card states explicitly that you are to have 40% of all fees (exclusive of hospital care, of course) received from your patients sent to our staff for operation or treatment. Hoping for an immediate and favorable reply, for which a stamped envelope is enclosed, I remain,

Most cordially yours,

Reduced facsimile of a letter sent out in 1912, soliciting the purchasing of stock in the "American Hospital" on a division of fee basis —forty-sixty!

At the time that the Medical Society of the United States was being organized—in 1916—there was published what purported to be a preliminary program of its first meeting. The meeting was held in St. Louis, and the program, while containing the names of men with special fads or interests to exploit, also contained the names of some men of standing. It appeared, however, on investigation, that at least some of the latter had but a hazy conception of the use to which their names were being put, and protested vigorously on learning the facts, repudiating the organization.

Now, in 1918, another drive is on for membership; letters signed "Emory Lanphear" are being sent to various selected groups of physicians. For example, the Eclectics are being coaxed by a letter which commences:

> "We want every reputable Eclectic practitioner in this country to join our society of protest against the iniquities of the A. M. A."

An identical letter has been addressed to Homeopaths, the words "Homeopathic practitioner" being substituted for "Eclectic practitioners." In all of the letters the "beautiful certificate of membership" is emphasized, and the trivial cost —"only $1.00 a year"—is referred to, while the plea: "surely you are willing to help to that amount to 'down' the 'gang' in charge of the A. M. A.," is featured. Another group of letters has gone out to the graduates of the Barnes Medical College. This commences:

> "Most graduates of 'Old Barnes' have joined our society of protest against the iniquities of the A. M. A. Why should you also not come in? It costs only $1.00 to become a member, including the cost of a beautiful certificate of membership."

Still another group appeal is based on sex; thus Lanphear:

> "We want every reputable 'lady physician' in this country to join our society of protest against the iniquities of the A. M. A."

And yet another:

> "You formerly belonged to the Tri-State Medical Society, of which I was Treasurer for 20 years. It is now dead. I wish you would join our new society which has superseded Tri-State in this territory."

With these various letters is enclosed a "preliminary program" of the 1918 meeting which is to be held October 8 and 9 in Chicago. As might be expected, many of the names on the program are characteristic of the organization and an interesting "story" might be made from the material in The Journal's files on the individuals. Such names are of men, who, professionally speaking, range from faddists, who ride grotesque and bizarre medical hobbies, to those who with special interests to exploit and unable to use reputable medical organizations for that purpose, take refuge in such hybrid conglomerations as the Medical Society of the United States. Not that the program contains the names of crude quacks, or obvious medical swindlers. It is representative, rather, of that twilight zone of professionalism, the penumbra, in whose uncertain light it is difficult to distinguish between the unbalanced visionary, with a fad, and the more sinister near-quack, with a "scheme."

Correspondence

"REPORT OF A CASE OF PRIMARY TUBERCULOSIS OF FAUCIAL TONSILS"

To the Editor:—In The Journal, Sept. 21, 1918, p. 968, there appears a "Report of a Case of Primary Tuberculosis of the Faucial Tonsils" by Major Oertel and Captain Griot. Without going into the subject of primary tuberculosis of the faucial tonsils, I should like to call attention to the fact that the report is far from convincing. As a matter of fact, it is rather self-contradictory. From the physical examination it would appear that the patient in question was suffering from advanced tuberculosis of the larynx and pulmonary tuberculosis. The laryngeal condition would indicate disease of rather long standing. The lung signs, although limited, do not preclude the possibility of more extensive disease of long duration. The laboratory report by no means clinches the diagnosis and describes nothing characteristic. That the mucus recovered from the larynx showed the presence of tubercle bacilli would further indicate very conclusively the presence of advanced pulmonary and laryngeal tuberculosis. Then why a case of primary tuberculosis of the faucial tonsils? Perhaps the authors have some more conclusive evidence for their remarkable statement.

Herman Schwatt, M.D., New York.

To the Editor:—In The Journal, September 21, there appeared a "Report of a Case of Primary Tuberculosis of the Faucial Tonsils" by Major T. E. Oertel and Capt. George A. Griot of Camp Logan, Texas. I am sure that on further study of this case the authors would not report it as one of primary tuberculosis of the faucial tonsils. That it was one of tuberculosis could not be questioned; but the history of the case, as given, would certainly lead us to class it as one of secondary tuberculosis following an infection in the lungs. The fact that the larynx and trachea showed such marked tuberculous changes would certainly preclude the possibility of knowing which was the first to be affected. My observations do not lead me to believe in even primary tuberculosis of the larynx, and I am sure it would be difficult to find a case of primary tuberculosis of the tonsil. These remarks are in no wise a criticism but merely a plea for more accurate deductions.

Dunbar Roy, M.D., Atlanta, Ga.

THE MEDICAL SECTION OF THE ADVISORY COMMISSION STILL BROADENING ITS FUNCTIONS

To the Editor:—According to the lay press, the chairman of the Medical Section of the Advisory Commission of the Council of National Defense has rushed in with the members of his Volunteer Medical Service Corps to take a hand in, if not to take charge of, the outbreak of influenza in the country. In Illinois, and I suppose in other states, he telegraphs his state chairman to appoint a committee to attend to the situation, and forthwith a committee for that purpose springs into existence.

What does this action mean? There are only two obvious answers. Either the usual constituted authorities for taking care of epidemics have failed, or the chairman of the Medical Section of the Advisory Commission is a sort of medical "all highest" in the United States, who is superior to all regular agencies and may step in when he sees fit.

We have for some time been accustomed to Colonel Martin's acting as though the Surgeon-Generals had to have some one to take over a considerable part of their functions in medical military affairs. But this excursion into administering the public health of the nation indicates a broadening of his self-appointed functions. Why this further assumption of authority? Have the usual federal, state and municipal authorities proved unequal to their duties? It is their specific function to take care of such situations. They are paid for it, and they have men especially trained for it. Has there been a breakdown in these agencies? Has Surgeon-General Blue gone in panic to Colonel Martin and appealed to him to help him out of a situation that the Public Health Service of the United States cannot handle for the country at large? Have the state boards of health and the municipal boards of health come crying to him for help or proved futile, that these new bodies should suddenly step in to assume their task, or show them how to do it, or without invitation to offer to help them do it?

There is no such crisis in the administration of our public health affairs. Even if there were such a crisis, is there any reason to believe that Colonel Martin is especially qualified to take care of the situation? He is not noted as a sanitarian, and the committees he appoints—if the Illinois committee is a sample—are not superior as sanitarians to our present regular officers. On his Illinois committee he interlards between busy practitioners the regular officers who ordinarily have charge of such work.

And one wonders how these officers feel about it. How do the Army and Navy and Public Health Service officers, the municipal and state health officers feel about sitting on these new committees suddenly formed to take over work that is usually up to them to do? I do not know how much open resentment there may be, but I think it would be hard to find a better illustration of mischievous meddling with other men's duties than this, or of actions tending more to confusion in the administration of public affairs and more to the lowering of the spirit of public officials.

If the newspaper publicity given to this action of Colonel Martin's—and the publicity was as great as usual and probably just as expensive—carries any implication to the public mind, it is that the usual authorities for looking after epidemics are unequal to their duty of taking care of this epidemic, and we must have a "god from the machine" come in to do it for them. This act, in fact, like Colonel Martin's attempt to force on the profession his Volunteer Medical Service Corps, is the act of one who apparently feels that he is a sort of national medical Pooh-Bah. The Medical Departments of the Army and Navy, the Office of the Provost Marshal-General, the Public Health Service, the offices of administration of state and local public health affairs—apparently all of these came within the scope of his functions—at least until the Provost Marshal-General announced last week that "membership in Volunteer Medical Service Corps is not service in the military establishment and does not therefore affect in any way the status of registrants before the Selective Service Boards."

It is a mischievous situation that Colonel Martin is forcing on us. The profession is confused by his actions. He has, I should estimate, sent probably a million letters to the profession under government frank about matters more or less connected with the war. Physicians do not know how authoritative these communications are. He has a way of writing—as he did in the case of his Volunteer Medical Service Corps, telling men to sign—as if he were clothed with federal authority to command, when, as a matter of fact, he is exploiting his own desires and plans; and physicians often do not know how much his communications represent federal authority and how much his own personal activities and views.

I am sure I sense the attitude of the profession when I say that its members are zealous in the highest degree to do all they can now for the public good, to know the wishes of the government in order to try to comply with them; that they accept instantly and without reservation—accept as orders—the communications of the Surgeon-Generals and the Provost Marshal-General. But—speaking now only for the profession of Chicago which I believe I know—a great many of them would prefer to get their orders and their instructions from the Surgeon-Generals of the Army, Navy, the U. S. Public Health Service and the Provost Marshal-General, who surely are competent to issue them.

William Allen Pusey, M.D.,
President of the Chicago Medical Society.

AN AUTHOR PROTESTS

To the Editor:—May I not thank you for the complimentary review of my book "Diet and Health with Key to the Calories" and at the same time take issue with your reviewer on the following points? He says: "By its title it assumes to be a parody on the guide of a well known religiomedical cult. This, however, appears only slightly in the text in the form of a few of the side headings." I fear he has missed the point that I have used their terminology throughout and my chapter of testimonies is a model of their literature. Furthermore, the reviewer says that the humor is a little forced. Again I differ with him. It is a great deal more than a little forced. It is very much forced, in fact almost forcibly forced. It has been killed, assassinated, annihilated, and dragged in most any place and any time. I did it purposely. Who reads an ordinary book on dietetics? Even a doctor will read mine!

Lulu Hunt Peters, Los Angeles.

Notification of Ophthalmia Neonatorum.—According to the *Medical Officer*, the local government board for Scotland has issued regulations under the public health act of 1897 for the compulsory notification of ophthalmia neonatorum in Scotland, dating from Nov. 1, 1918. Although no direct arrangement is made by the local government board for treating and following up these cases, it is pointed out that this follow-up work might properly come under the duties assigned to health visitors under the regulations relating to maternity service and child welfare, and that the child welfare grant is available for this purpose. It is therefore hoped by the board that the local authorities will avail themselves of this resource and see that all notified cases of ophthalmia neonatorum receive immediate treatment. The Royal Commission on Venereal Diseases reported that probably 25 per cent. of all cases of blindness are due to ophthalmia neonatorum, and that probably 50 per cent. of all blindness is due to the venereal diseases, syphilis being a prolific cause.

Queries and Minor Notes

Anonymous Communications and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

PRINTING OF HARRISON NARCOTIC REGISTRY NUMBER ON PRESCRIPTION BLANKS

To the Editor:—Some time ago I went to the expense of having 5,000 prescription blanks printed and bound containing my name and address, also my registration number under the Harrison Narcotic Law. My druggist informs me that when writing a narcotic prescription it is necessary for me to append under my signature my registry number, address and date, and that having the number and address printed on them will not comply with the law. Please let me know if he is correct.

Z. S. H., Kentucky.

Answer.—In the Harrison Narcotic Law and regulations issued by the Treasury Department as Internal Revenue Regulations No. 35, Section 2 B, it is stated that "such prescription shall be dated as of the date on which signed and shall be signed by the physician, dentist or veterinary surgeon who shall have issued the same." Article 11 of the regulations states that "drugs dispensed or distributed under and in pursuance of a written prescription issued by a physician, dentist, or veterinary surgeon duly registered under the act must show the name and address of the patient, the date, the name and address of the physician, and his registry number. . . . All prescriptions must be dated and signed on the date when issued." It is, therefore, necessary for the physician to write only the date and signature. The name, address and registry number may be printed on the prescription blank.

CALCIUM CHLORID ANTIFREEZE MIXTURE

To the Editor:—In Queries and Minor Notes (The Journal, Aug. 31, 1918, p. 768), in discussing the use of calcium chlorid solutions to prevent freezing in automobile radiators, you stated incidentally that such solutions have a harmful effect on the radiator, especially on seams and joints. The following amplification of the statement may be of interest to your readers:

At the temperatures in question, calcium chlorid solutions have a decidedly harmful effect on the radiator, not only on the seams and joints, but also on the whole metal surface. The effect is, of course, usually more apparent at the seams and joints. No one who has not studied this effect perhaps realizes the extent of the pitting and corrosion produced. The effect is, of course, produced through the appreciable hydrolysis of the salt in question at the boiling temperature.

Commercial antifreeze mixtures generally contain chiefly or wholly calcium chlorid or some substance as harmful in its effect. The only safe method is to employ an alcohol-water mixture, which is perfectly harmless. The extra trouble involved, through continual evaporation or expense difference, is more than compensated by the saving in possible radiator repairs.

Stanley L. Chisholm, Washington, D. C.
Sergeant, First Class, Chemical Warfare Service, U. S. Army.

WAR BILLS OF PHYSICIANS

The following is a copy of a card sent to his patients by an Indiana physician about to go into military service:

"LIBERTY STATEMENT"

M................................

I am sending you this statement because I am expecting to leave soon and must ask that you call at once and settle your account. It is absolutely necessary that I collect all my outstanding accounts in order that I may meet my own financial obligations and make arrangements for my family during my absence in the Army.

I prefer to settle all accounts personally rather than leave them in the hands of an Agent or Attorney. I will expect to hear from you at an early date.

Respectfully,

....

SUGAR TREATMENT OF TUBERCULOSIS

To the Editor:—Please give me some information concerning a tuberculosis cure called "Lo Monaco," which is being recommended here by the official Public Health Service. The substance comes in tablets to be dissolved, boiled and injected intramuscularly. I have been unable to get any information about the true nature of this remedy, and do not remember having read anything about it in The Journal.

M. P. Colmenares, M.D., Orizaba, Vera Cruz, Mexico.

Answer.—A discussion of this subject appears in Queries and Minor Notes, The Journal, Sept. 28, 1918, p. 1083.

Medical Education and State Boards of Registration

COMING EXAMINATIONS

Arkansas: Little Rock, Nov. 12-13. Sec., Regular Bd., Dr. T. J. Stout, Brinkley, Ark.; Sec., Eclectic Bd., Dr. C. E. Laws, 803½ Garrison Ave., Ft. Smith.

California: Sacramento, Oct. 21-24. Sec., Dr. C. B. Pinkham, Butler Bldg., San Francisco.

Connecticut: New Haven, Nov. 12-13. Sec., Regular Bd., Dr. C. A. Tuttle, 196 York St., New Haven; Sec., Eclectic Bd., Dr. James E. Hair, 730 State St., Bridgeport; Sec., Homeopathic Bd., Dr. E. C. M. Hall, 82 Grand Ave., New Haven.

District of Columbia: Washington, Oct. 8. Sec., Dr. Edgar P. Copeland, The Rockingham, Washington.

Georgia: Atlanta, Oct. 8-9. Sec., Dr. C. T. Nolan, Marietta.

Kansas: Topeka, Oct. 8-9. Sec., Dr. H. A. Dykes, Lebanon.

Maine: Portland, Nov. 12-13. Sec., Dr. Frank W. Searle, 776 Congress St., Portland, Me.

Massachusetts: Boston, Nov. 12-14. Sec., Dr. Walter P. Bowers, No. 1 Beacon St., Boston, Mass.

Michigan: Lansing, Oct. 8-10. Sec., Dr. B. D. Harison, 504 Washington Arcade, Detroit.

Nevada: Carson City, Nov. 4. Sec., Dr. S. L. Lee, Carson City.

New Jersey: Trenton, Oct. 15. Sec., Dr. Alex. MacAlester, 438 E. State St., Trenton.

New Mexico: Sante Fe, Oct. 14. Sec., W. E. Kaser, East Las Vegas.

Oklahoma: Oklahoma City, Oct. 8-9. Sec., Dr. J. J. Williams, Weatherford.

Texas: Dallas, Nov. 19-21. Sec., Dr. M. F. Bettencourt, Mart.

Utah: Salt Lake City, Oct. 7-8. Sec., Dr. G. F. Harding, 405 Templeton Bldg., Salt Lake City.

West Virginia: Charleston, Nov. 19-21. Sec., Dr. S. L. Jepson, Masonic Bldg., Charleston.

Utah April Examination

Dr. G. F. Harding, corresponding secretary of the Utah State Board of Medical Examiners, reports the written examination held at Salt Lake City, April 2-3, 1918. The examination covered 19 subjects and included 100 questions. An average of 75 per cent. was required to pass. Four candidates were examined, all of whom passed. The following colleges were represented:

College	PASSED	Year Grad.	No. Licensed
Chicago College of Medicine and Surgery		(1917)	1
Western Reserve University		(1917)	1
Jefferson Medical College		(1917)	1
University of Pennsylvania		(1917)	1

Dr. Harding also reports that 2 candidates were licensed through reciprocity at the meeting held, April 5, 1918. The following colleges were represented:

College	LICENSED THROUGH RECIPROCITY	Year Grad.	Reciprocity with
University of Louisville		(1916)	Kentucky
Vanderbilt University		(1913)	New York

Maryland June Examination

Dr. J. McP. Scott, secretary of the Board of Medical Examiners of Maryland, reports the written examination held at Baltimore, June 18-22, 1918. The examination covered 9 subjects and included 90 questions. An average of 75 per cent. was required to pass. Of 56 candidates examined, 51 passed and 5 failed. Eighteen candidates were licensed through reciprocity and one was granted a reregistration license. The following colleges were represented:

College	PASSED	Year Grad.	Per Cent.
Howard University (1917) 80; (1918) 76, 91, 92.			
Indiana University		(1917)	84
Johns Hopkins University (1914) 87; (1915) 90; (1917) 80, 82, 83, 84, 85, 86, 91; (1918) 80, 83, 83, 84, 84, 85, 86, 87, 87, 87, 88, 88, 88, 89, 89, 90, 91, 92, 92, 94.

Michigan June Examination

Dr. B. D. Harison, secretary of the Michigan State Board of Registration in Medicine, reports the written examination held at Ann Arbor, June 11-13, 1918. The examination covered 14 subjects and included 100 questions. An average of 75 per cent. was required to pass. Of 76 candidates examined, 75 passed and 1 failed. Twenty-nine candidates were licensed through reciprocity. The following colleges were represented:

College PASSED	Year Grad.	Per Cent.
Johns Hopkins University	(1918)	85.8

Book Notices

Biochemical Catalysts in Life and Industry. *Proteolytic Enzymes.* By Jean Effront, Professor in the New University and Director of the Institute of Fermentations of Brussels. Translated by Samuel C. Prescott, Professor of Industrial Microbiology, Massachusetts Institute of Technology, assisted by Charles S. Venable. Cloth. Price, $5. Pp. 752. New York: John Wiley & Sons, 1917.

This is a discussion of biochemical catalysts or enzymes for nitrogenous substances only. Though the greater part of the text deals with the enzymes for protein substances as found in the digestive secretions of the animal body, the proteases of animal and plant tissues and bacteria are likewise considered. A sixth of the book deals with the coagulating enzymes (thrombin, myosinase and rennet). The greater part discusses pepsin, the various trypsins and erepsins, and the amidases. One hundred and seventy-five pages are devoted to the use of the various enzymes in bread making, brewing, distilling, the manufacture of cheese, tanning, and in agriculture. The distribution, methods of preparation and mode of action of the various enzymes under different experimental conditions are fully and accurately considered. The excellence of the book on that score can hardly be questioned. It is gratifying, furthermore, to have at hand a ready reference book of small size in which the practical usefulness of the nitrogenous enzymes to industry is adequately considered. The parts of the book dealing with the mechanism of secretion of gastric and pancreatic juice are disappointing. Following Pawlow and his pupils, the author takes the view that the fasting stomach contains "very little juice normally." As a result of this erroneous conception, the importance of psychic or appetitic (nervous) juice is greatly overestimated. Gastric secretin or gastrin receives no mention. The physician will certainly find the parts of the book dealing with mechanical physiology quite fragmentary. It is to be regretted that the author did not incorporate the results of American research on sundry questions relating to the activity of the digestive glands. Although the study of the coagulation of the blood has been made the subject of a particularly important chapter "benefiting from recent acquisitions," not a single reference is made to the careful and interesting work of the American physiologist, Howell. The preliminary work of Howell's pupil, Rettger, is mentioned, but his publication is cited in the bibliography with a German title, although it is published in English. The important work of Howell himself (and his pupils) contained in ten or twelve original papers is not even alluded to.

Chemistry of Food and Nutrition. By Henry C. Sherman, Ph.D., Professor in Columbia University. Second edition. Cloth. Price, $2. Pp. 454, with 16 illustrations. New York: The Macmillan Company, 1918.

In the presentation of his theme the author discusses first the chemical nature and the nutritive functions of the substances that serve as sources of energy in nutrition; then the nutritive requirements in terms of energy; protein; the more prominent inorganic elements and the vitamins, and finally the bearing of the various factors of food value on the problems connected with the economic use of food. Such is the scope of a work that has deservedly reached a second edition and will in the years to come reach many more because of its logical and simple style, its accuracy, and its delightful presentation. Every physician who wishes to inform himself in a general way of the present status of our knowledge of the nutrition of man will find the book a short but invaluable and reliable text giving all essential facts. The excellent bibliography makes it readily possible to obtain information in greater detail on any desired topic. Whereas, most of the facts concerning the nutritional importance of proteins, carbohydrates and fats are found in other texts, the latter are wofully deficient in a discussion of the inorganic foodstuffs and in mineral metabolism (chlorin, sulphur, phosphorus, sodium, potassium, calcium, magnesium and iron). We know of no other book of moderate size that deals so thoroughly with these essentials to nutrition. Approximately 176 pages are devoted to the inorganic foodstuffs, and justly so; for, as the author reminds us ten of the fifteen elements or seven of the twelve that are essential in amounts sufficiently large to be measurable by present methods, must be furnished by some ingredients of the intake other than the simple proteins, carbohydrates and fats. In this discussion the element iodin is undeservedly slighted. The American physician will note with pride that the significant advances in metabolism and nutrition during the last decade or more have for the most part been made by American investigators. The book embodies the important results in this field of Lusk, Atwater, F. G. Benedict, Osborne, Mendel, Van Slyke, Folin, Hart, McCollum, Chittenden, Du Bois, Forbes and Sherman himself. There is no excuse for any physician to remain unfamiliar with the important and interesting work of these men, when their work is presented comprehensively and yet most interestingly in a volume of moderate size and small cost.

The Hodgen Wire Cradle Extension Suspension Splint. The Exemplification of This Splint with Other Helpful Appliances in the Treatment of Fractures and Wounds of the Extremities and Its Application in Both Civil and War Practice. By Frank G. Nifong, M.D., F.A.C.S. With an introduction by Harvey G. Mudd, M.D., F.A.C.S. Cloth. Price, $3. Pp. 162, with 124 illustrations. St. Louis: C. V. Mosby Company, 1918.

This book describes the methods of application and uses of the Hodgen extension and suspension splint. This splint, it is pointed out in the historical introduction, was described by Professor Hodge at the time of the Civil War as a modification of the Nathan R. Smith anterior splint for fractures of the thigh. The author discusses the general mechanism of fractures of the femur, splints for immobility and extension, splints for immobility and suspension, splints for immobility, extension and suspension, and the Hodgen extension suspension splint. The final chapter is devoted to the use of accessory appliances. It is a practical little book.

A Text-Book of Elementary Military Hygiene and Sanitation. By Frank R. Keefer, A.M., M.D., Colonel, Medical Corps, United States Army. Second edition. Cloth. Price, $1.75 net. Pp. 340, with illustrations. Philadelphia: W. B. Saunders Company, 1918.

Colonel Keefer's textbook was prepared primarily for the instruction of cadets at the United States Military Academy at West Point, and is adapted chiefly for the uses of the officer of the line rather than for the medical officer. Since the first edition was issued in 1914, the new type of warfare has necessitated considerable changes in this book, particularly the problems of trench sanitation. These problems are considered in a special chapter. The book is brief yet complete, and written in plain language so as to be readily understood by any man qualified to hold the rank of officer in our army.

Military Surgery of the Zone of the Advance. By George de Tarnowsky, M.D., F.A.C.S., Major, M. C., U. S. R. Leather. Price, $1.50. Pp. 330, with illustrations. Medical War Manual No. 7. Philadelphia: Lea & Febiger, 1918

The author's foreword modestly states that this is not a textbook on military surgery, but a vade mecum on the treatment of war wounds. But the difference between this and a textbook is that theories and nonessentials are here omitted, and that essentials are concisely presented. It is a practical, complete handbook for the Army surgeon on the transportation and management of the wounded and the methods of treatment that have been tried out and found satisfactory in the Allied armies during the four years of the war. It is based on personal observation by the author on the French, British and Italian fronts; hence it is up to date and represents the methods and procedures of today.

The first six chapters are devoted to a general description of the terrain of the French and British zone of advance, including description of first-aid station, transportation equipment, regimental-aid, station, field hospital, etc. In separate chapters are described the bacteriology of war wounds, traumatic shock, tetanus, gas bacillus gangrene, spinal injuries, burns, gas poisoning, the Carrel-Dakin technic; wounds of the face and neck, of the thorax, of the abdomen, of the bladder and external genitalia, of peripheral nerves, of soft tissues. In fact, the whole field of surgery, so far as it might be met in war work, is covered. While condensation and conciseness in statements evidently have governed the author, at the same time, this has not hindered the giving of the necessary details for a clear understanding of the subject discussed. The purpose has been to have a large amount of material in a small space; hence the page is full—there is no padding, no waste margin at the top, bottom or sides, and no leading. The book is printed on thin paper, and while it contains 330 pages it can easily be carried in the pocket.

Medicolegal

Husband Liable for Medical Services Only Not Shown Bound by Payment

(Vaughan v. Mansfield (Mass.), 118 N. E. R. 652)

The Supreme Judicial Court of Massachusetts, in sustaining exceptions to a verdict for the plaintiff, says that it was not in dispute that the medical services for which the plaintiff sought compensation were required by, and were rendered to, the wife and minor child of the defendant as claimed. The evidence warranted a finding that the defendant had seen the plaintiff at the defendant's house and that he knew the visits there were made by the plaintiff, as a physician, in response to calls from the wife of the defendant. There was also evidence that the plaintiff had sent bills from time to time to the defendant's residence, through the mail. There was no evidence that the defendant ever had forbidden the plaintiff to render, or the wife or child in the presence of the plaintiff to receive, the services of the plaintiff, on his account. It followed that a charge in this regard to the jury was sufficiently favorable to the defendant, which was that "a husband is required to furnish the necessaries to his wife and minor child, and he is liable for the necessaries furnished to his wife and child when they live with him, and if the plaintiff's services were necessary to the defendant's wife and minor child, the defendant would be liable for their reasonable cost." And this disposed of the exception of the defendant to a refusal to rule that "the defendant was not liable to the plaintiff for this bill, even if it was for necessaries furnished to his wife and minor child, unless the defendant refused or failed or neglected to furnish them himself."

Under these circumstances the presumption of the agency of the wife, which is inferred from her relation to her husband as manager of the household, to pledge her husband's credit for medical services that are reasonably necessary for her or the family, was not rebutted by proof that the defendant privately had instructed his wife never to run any bills, and had given her money from time to time to pay all expenses when she told him she needed it.

But, in answer to the defense that the action was barred by the statute of limitations, the plaintiff merely testified that "he had received a payment of five dollars" on account in July, 1908. He offered no evidence to prove that the payment was made by the defendant, by the wife of the defendant, or by any one who had authority to act for the defendant. The court is of the opinion that this testimony went no farther than proof of payment by a stranger, and was insufficient as evidence for a jury to find an acknowledgement on the part of the defendant of a subsisting liability; and the court thinks that the jury should have been so instructed.

What Is an "Accident" or "Accidental"

(Lickleider v. Iowa State Traveling Men's Association (Ia.), 166 N. W. R. 363)

The Supreme Court of Iowa says that one thing at least is well settled: The words "accident" and "accidental" have never acquired any technical meaning in law, and when used in an insurance contract they are to be construed and considered according to the common speech and common usage of people generally. Hundreds of attempts have been made by the courts to define these words in other terms, and while some of them may be regarded helpful so far as they adhere to popular usage, others have served only to confuse the situation, if not in fact grossly to mislead. Certain it is that no attempt in this direction is in any respect an improvement on the definition found in our standard lexicons. It is an event from an unknown cause or an unexpected event from a known cause; a thing done or disaster caused without design or intention; an unusual and unexpected result attending the performance of a usual or necessary act.

There is, however, another alleged definition which has had a degree of judicial sanction which ought not to be passed without notice. According to this definition, an injury happening to an insured person through his own voluntary act is not an accident, nor is his hurt to be attributed to accidental means—a proposition that is wholly at variance with every statement of the true rule. It may be, and it is true, that if the insured does a voluntary act, the natural, usual and to be expected result of which is to bring injury on himself, then a death so occurring is not an accident in any sense of the word, legal or colloquial, and it is only when thus limited that the rule so stated has any proper application. It makes no difference whether the injured man or some other person voluntarily sets in motion the first of a series of events which in connected line of causation results in his injury or death. If the resulting injury and violence to him "unexpectedly took place," or was "an unexpected result from a known cause," or was produced "without design or intention," or was "an unusual and unexpected result attending the performance of a usual or necessary act," or was an "event happening without the concurrence of the will of the person by whose agency it was caused," or if it was "caused or produced without design," it falls directly within the letter and spirit of the definition that has been placed on the words by the most competent lexicographers as well as by our most eminent jurists who have given the matter attention.

In this case a holder of a policy or certificate of accident insurance issued by the defendant, in attempting to remove an automobile tire which for some reason resisted his efforts, knelt on one knee, took hold of the casing with both hands, pulling and jerking at it for some time, when it came off with a snap and such suddenness as to cause him to slip or stagger back with the tire in his hands. He immediately turned pale, complained of being very ill, put his hand to his head, and lay down on the ground. Help was called, but he died about an hour later. A postmortem examination was made of the body by three physicians, who found that the immediate cause of death was a blood clot in the right coronary artery near the heart. Two of the physicians attributed the death to arteriosclerosis, while the third found no more arteriosclerosis than is usual with a man of such size and age. The court holds that a case was made on which the plaintiff was entitled to go to the jury, and that it was error to direct a verdict for the defendant. If the arteries of the insured were sclerotic, but the sclerosis was only such as is the natural or usual accompaniment of increasing years, the fact, if it was a fact, that a bodily injury sustained by him would more likely be fatal than would be the case if such condition did not exist would not prevent a recovery on the policy should it otherwise appear that the injury was of the nature or kind described in the contract.

Liability for Malpractice in Performing an Illegal Operation

(Lembo v. Donnell (Maine), 103 Atl. R. 11)

The Supreme Judicial Court of Maine, in overruling exceptions to a ruling that overruled a general demurrer filed by the defendant, says that this was what is termed an action on the case brought to recover damages against the defendant, a physician, for malpractice while performing an operation to procure an abortion on the plaintiff, and for unskilled treatment subsequent to the operation. The basis of the defendant's exceptions lay in his position that as the plaintiff consented to the operation she could not recover damages because the operation was an illegal one. In a similar case, *Miller* v. *Bayer,* 94 Wis. 123, 68 N. W. 869, the court said:

> It is further contended that plaintiff cannot recover, because she submitted to the operation performed on her. Such is not the law. Consent by one person to allow another to perform an unlawful act on such person does not constitute a defense to an action to recover the actual damages which such person thereby received.

This court agrees that this statement of the law is correct.

KENTUCKY STATE MEDICAL ASSOCIATION

Sixty-Eighth Annual Meeting, held at Louisville, Sept. 4-6, 1918

The President, Dr. J. S. Lock, Maysville, in the Chair

Diagnosis of Gastric and Duodenal Ulcer

Dr. J. A. Sweeney, Louisville: Other and older methods must not be discarded for the roentgen ray although it is of great value in demonstrating the size, location, and character of the ulcerations.

The operator with the greatest experience in stomach surgery and surgical pathology, is more likely to interpret correctly that which he encounters in the gastric area, than one who has had less experience, which, no doubt, accounts for the very large number of ulcers diagnosed by some surgeons, as compared to others, and the varying statistics as to the frequency of the ulcer.

DISCUSSION

Dr. C. W. Dowden, Louisville: There is only one method by which gastric and duodenal ulcer can be diagnosed positively, and that is roentgenography. There are absolutely no symptoms that might be referred to a gastric or duodenal ulcer that cannot come from disease of the pancreas, the gallbladder, or even the appendix. While I may diagnose pyloric obstruction, I always reserve the right to say that the trouble may be due to an ulcer, to disease of the gallbladder or appendix. In a number of instances pyloric obstruction may be present with little defect of the pylorus or duodenum, and at operation no ulcer is found; but there is a diseased gallbladder with or without stones, or possibly dense adhesions which disturb the normal contour of the duodenum, and which present difficulties in diagnosis.

SYMPOSIUM ON CHRONIC INTERSTITIAL NEPHRITIS

Etiology

Dr. F. H. Clarke, Lexington: I believe clinicians agree with Rosenstein that in the great majority of cases of primary chronic interstitial nephritis, the genuine contracted kidney, the cause is unknown. Heredity and age doubtless play a prominent part. There is considerable evidence of an hereditary tendency or susceptibility to kidney disease. I have noticed this in my own experience. It is generally conceded that the active cause or causes of chronic nephritis are in the blood; that the blood contains the toxic material which may produce the morbid changes in the kidneys. Probably the same toxic agents, when present in the blood in large quantities, may produce a rapid and severe toxemia which terminates in an acute inflammation. When present in less quantity and acting slowly these toxins may bring about a chronic nephritis without the acute stage. Aside from its hereditary influence, syphilis does not often have an active part in causing contracted kidney directly. Its influence in causing arteriosclerosis makes it prominent in the related type of nephritis, but the other forms are rarely directly produced by it. Gout is said to be a common cause of chronic nephritis, and English physicians put special stress on it as a cause of chronic interstitial nephritis.

Cardiovascular Changes

Dr. B. C. Frazier, Louisville: Often cardiovascular changes are not observed for a long time after the onset of persistent albuminuria. It is of special importance in cases of chronic or even acute albuminuria to look for vascular changes, especially in the middle-aged and elderly, and noting the blood pressure. From a diagnostic point, cardiovascular changes in nephritis are of as much importance as the study of the urine. It is very difficult, especially in the late stages of chronic interstitial nephritis, to decide whether it is primarily a heart or a kidney case. Increase of heart size varies. At first there may be only enlargement of the left ventricle mainly with apex displacement downward and to the left. Later, there is often enlargement of the right ventricle, with the apex impulse diffused and heaving. In more advanced cases, a presystolic murmur is often present. The peripheral vessels are hard and tortuous. A tortuous and plainly visible temporal artery is good evidence of underlying renal disease.

Many of the phenomena of chronic interstitial nephritis are explained by uremia. These toxic symptoms may be mild and of long standing, or they may be of sudden onset, the severe headache and convulsion coming without warning, frequently followed by fatal coma, an acute uremia. Inspection is frequently all that is needed to make one suspect malignancy or a chronic and rapidly developing nephritis with vascular changes.

Symptom Complex

Dr. R. Hayes Davis, Louisville: In the early part of the disease the only changes noted are an increase in blood pressure and hypertrophy of the heart, involving only the left ventricle at first. The extent of these changes is variable. The blood pressure may be nearly normal or only slightly elevated or it may be quite high, and the heart shows hypertrophy varying from only a slight enlargement with an increase of the first sound and a slight accentuation of the aortic sound to an actual ox-heart. As the disease advances these changes gradually become more marked, and if the patient is destined to progress along the cardiac route, he will sooner or later develop the symptoms of dilatation which occur as a result of an overworked heart muscle degenerated on account of coronary sclerosis and fatigued from its efforts to force the blood through inelastic arteries against a high blood pressure, or handicapped by diseased valves. The symptoms of dilatation progress from slight irregularities, and dyspnea on exertion with dizziness and digestive disturbances, etc., to the extreme forms of cardiac failure with marked dyspnea, weak heart, edema, and all the other distressing symptoms. Uremia may manifest itself as a chronic form of intoxication or as an acute overwhelming toxemia. The so-called chronic forms of uremia are most common. Perhaps, the most frequent symptom is headache. This may be slight or very intense, in some cases resembling migrain. Chronic headaches beginning in individuals past middle life, or migrain attacks that grow worse instead of better, should be looked on with suspicion. Digestive disturbances are frequent. Vomiting may be typically centric in origin and may resemble the vomiting of brain tumor. Various forms of transient paralyses often occur, involving the face, the tongue or one or more extremities. They are usually of very short duration.

Laboratory Findings and Their Value

Dr. C. W. Dowden, Louisville: Fluid retention (persistent), with nocturia and fixation of specific gravity offers the simplest and most trustworthy evidence of potential nephritis and its correction will prevent actual disease. Nephritis is manifested further by (a) an increase in the constant Ambard or the index of McLean; (b) retention of nitrogenous products in the blood, first of uric acid, second of urea, and third of creatinin, as the process progresses; (c) a low excretion of phenolsulphonephthalein, generally, or excretion above 80 per cent. with other evidences; (d) hypertension, in the interstitial type particularly until the myocardium fails. Diagnosis is possible in 100 per cent. of cases if all these methods are employed. Prognosis of death in two months is possible in 100 per cent. of cases with creatinin retention of 5 mg. or more per hundred c.c. of blood.

Cardiovascular Changes; Medical Management

Dr. J. A. Flexner, Louisville: The origin of the vascular, cardiac and renal changes which mark the earliest stages of this condition lies in some infectious process, either acute or chronic. The kidneys are the great emunctory organs for the chemicotoxic products which result from the bacterial destruction of tissues as the result of infectious processes; there is scarcely an infection of any severity which does not have an albuminuria and other evidences of destructive processes in the kidney accompanying it. These toxic substances are carried to these organs by the blood stream, hence we can understand the damage done to the vessels, and especially the renal vessels by reason of the concentration of the poisons in the kidney. In the management of these cases elimination of infectious processes is the first step in treatment. Conserve the reserves of function left in these organs, so that no organ will be overstrained or given a load to carry for which it has been rendered unfit. By living well within their physiologic resources many of these patients may have long and useful lives.

DISCUSSION ON SYMPOSIUM ON NEPHRITIS

Dr. Frank W. Fleischaker, Louisville: Physicians speak of chronic parenchymatous nephritis and chronic interstitial nephritis, but the pathologist says we are dealing with a large, white kidney, or a secondarily contracted kidney, or with a gouty kidney or an arteriosclerotic kidney, or a senile kidney. But that makes little difference if we know what we mean by chronic interstitial nephritis in contradistinction to chronic parenchymatous nephritis. That is all that is necessary. We understand the production of it. When we think of chronic interstitial nephritis we at the same time think of cardiac changes. It is not of much moment whether the pathology of the heart or the pathology of the kidney is primary. They seem to go hand in hand and physicians speak of these cases as cardiorenal.

As to the prognosis and treatment, it does not make much difference whether one or the other originated first; we take the symptoms as they come for the treatment.

Dr. C. I. Sherman, Millwood: Suppose the specific gravity of a certain urine is 1.010; we examine the urine again and find it still 1.010, and so on for a number of times. Then, suppose we increase the proteids and decrease the liquids but the specific gravity still remains 1.010. That kidney may be able to excrete a certain amount of urine if you take away the liquids and increase the solids. I think that is what the essayist means by a fixed specific gravity. That is one of the early symptoms. We all ought to employ the phenolsulphonephthalein test.

Dr. John R. Morrison, Louisville: We know that infectious diseases are often the foundation for nephritis. We should also consider focal infection that comes from the teeth, the tonsils, the sinuses and the prostate. The prostate is often overlooked. It may be the source of infection and the cause of back pressure on the kidneys. In such cases, when the back pressure on the kidneys has been relieved, the symptoms of chronic interstitial nephritis often clear up.

Dr. C. W. Dowden: Dr. Sherman misunderstood me in regard to the question of fluid retention being one of the early signs of nephritis. As a matter of fact, in interstitial nephritis or compensated nephritis, the output of fluid is in excess of the intake because, owing to lack of concentrative power, nature calls on the kidney for a greater output to make up the deficiency. In the later stages of interstitial nephritis and nephritis, when the burden of the kidney is transferred to the heart and myocardium, parenchymatous nephritis and retention of all nitrogenous products appear. This means myocardial failure. Low specific gravity means that the kidney is doing its work all right in interstitial nephritis, but fixation of a high specific gravity means a congested kidney, or in the later stages when the myocardium fails it is of doubtful significance.

Focal Infection from a Dental Standpoint

Dr. Raymond Grant, Louisville: I cannot condemn too emphatically the practice of physicians who advise patients to have all their teeth removed, simply because it is recognized that some of them may have to be sacrificed. Where there is a focus of infection in any of the anterior teeth, it is possible to effect a cure in a great majority of instances either by the therapeutic action of drugs or by surgical procedures.

Hyperthyroidism: A Clinical Study

Dr. W. F. Boggess, Louisville: Close watching and careful analysis of a large number of persistent tachycardias, without any perceptible increase in the size of the thyroid gland, but with persistent disturbances of metabolism, loss of strength, increased nervousness, will unearth a large number of unsuspected atypical hyperthyroideas with the cardiovascular symptoms remaining in the ascendency. The treatment of the thyrotoxicosis is not the treatment of the heart or any one distressing symptom, but the treatment of the condition in its entirety. Find the focal infection, if it exists, and remove it.

After thorough study and diagnosis of these atypical cases, the results of medical treatment are very favorable. From 70 to 90 per cent. of the patients can be relieved and cured. I do not desire to minimize in the slightest, the wonderful results of surgery, and the necessity of surgery in many cases of exophthalmic goiter, but I do want to emphasize the fact that these cases should be recognized early, and that proper treatment should be instituted early, and the patients prevented from coming to the surgical stage. Do not postpone surgical intervention until the general musculature, as well as the cardiac muscle, has been degenerated to such a point that even surgery fails.

Uterine Prolapse with Cystocele

Dr. John R. Wathen, Louisville: The Watkins operation of interposition of the bladder, consists of placing the bladder so that it rests on the posterior surface of the uterus, and the uterus is fixed to the anterior vaginal wall, acting as a buffer against any descent of the bladder. The uterus is fixed in a position from which it can never retrovert or markedly descend or prolapse; for retroversion is the first step in the development of a marked ptosis or prolapse of the uterus. The best results from this operation are obtained in cases where there is a firm uterus of average size. The brilliant results obtained from this operation cause me to feel that the general practitioners and the surgeon should have a better appreciation of its possibilities and merits.

DISCUSSION

Dr. W. Barrow, Lexington: I have had experience with this operation in over forty cases, twenty-three of which were my own, and of that twenty-three there was a cure effected in twenty-one. In one of the cases I operated a second time and found tuberculous peritonitis. I suppose that is the reason why the uterus did not hold. There are two or three things about the operation that are important. First, complete separation of the bladder. If you separate the bladder incompletely you will have little pockets that are adherent to the uterus when you attempt to operate through the abdomen, and these will cause a marked cystitis which it is difficult to cure. It is necessary to curet the uterus. These uteri are usually large and subinvoluted, practically always retroverted, and curettement stimulates the return of the uterus to the natural size. I think it is also necessary to amputate the cervix even though it is short.

Hemorrhage in the Common Nose and Throat Operations

Dr. S. G. Dabney, Louisville: The fear of hemorrhage need very rarely deter us from operating about the nose and throat. In plethoric adults, especially those of short neck and heavy build, it is well to give the chlorid or lactate of calcium a few days before operating. If this is not practicable, a half grain of emetin given hypodermically or pituitary extract may be administered just before the operation. In all cases it is wise to see that the patient is free from any recent acute inflammation, is in good condition and that the bowels are open. To obtain the full effect of epinephrin and cocain in the nose, a pledget of cotton soaked in these solutions should be left in situ for from half an hour to an hour. Nasal plugging is undesirable, and except for temporary purposes while operating under general anesthesia, it is not often necessary. When plugging is done, the packs, and especially the posterior ones, should never be left in place more than twenty-four hours. Of the internal measures to control nose and throat hemorrhage, morphin and atropin are among the most valuable drugs. If a spurting vessel is seen after a tonsil operation, it should be caught in the artery forceps, and, if necessary, torsion practiced. Ligation is rarely called for. If the hemorrhage comes from persistent oozing, as observed after retracting the anterior pillar and carefully examining the fossa, pressure either with the gauze on the forefinger or by means of a sponge, will usually arrest it. A hot sponge may be more valuable and especially one dipped in a hot solution of calcium chlorid or a 5 per cent. solution of gelatin in normal saline. If the hemorrhage is severe, sewing the anterior and posterior pillars together, possibly with a little piece of gauze between them, may be called for. Postoperative hemorrhage is often manifested by the vomiting of blood. When the blood appears fresh and red it would indicate that the bleeding is still going on, but it is well to remember that vomited blood seems far more than it is and the pallor and exhaustion may be due to nausea. In rare instances, it may be necessary to return the patient to the operating room and under general anesthesia search for the bleeding spot and use some of the surgical procedures mentioned, giving at the same time, if very urgent, a subcutaneous injection of epinephrin in normal saline and remembering that cases are reported where ligation of the carotid has been called for.

DISCUSSION

Dr. W. B. McClure, Lexington: No operation should be done on the throat following an acute inflammation of this region. The only fatality I have any knowledge of followed a tonsillectomy in which there was an acute inflammation of the tonsils. These hemorrhages are frequently due to the fact that in the operation we wound the pillars and thus produced a bleeding surface. In my own experience in tonsillar work I have never yet had to return a patient to the operating room for a second anesthesia, and I have rarely met with cases in which the bleeding was not controlled by pressure.

Dr. J. G. Carpenter, Stanford: These hemorrhages generally occur in the hyperplastic tonsil, unless the patient is a bleeder. By compression with forceps and a little torsion or ligation you can control the hemorrhage. In addition to tannic acid and gallic acid, you will find antipyrin, 15 grains to the ounce, a wonderful local hemostatic in tonsillar, throat and nasal surgery.

Dr. M. F. Coombs, Louisville: No menstruating woman should be operated on; we should wait until the period is over, at least ten days, before operating. A most excellent hemostatic is hot alum water.

Dr. Cowley, Berea: Local anesthesia for tonsil work has taken away almost all the terrors of hemorrhage for me. I have not had a case of hemorrhage since I have used local anesthesia, and I have done two operations on children 7 years of age under local anesthesia. A local anesthetic gives one a chance to see what he is doing.

Traumatic Injuries of the Chest

Dr. W. L. Gambill, Jenkins: The treatment is expectant unless infection, hemorrhage or respiratory embarrassment threaten life. The patient should be placed in a position of greatest comfort and ease of respiration. Shock should be treated by heat, stimulants, pituitary extract, epinephrin and, if severe, by intravenous salines or hypodermoclysis. In case of injury to the pleura or lung, adhesive plaster strapping affords marked relief. Aspiration may be necessary in pneumothorax or hemothorax if respiration is seriously embarrassed. Should empyema develop, thoracotomy and drainage must be instituted.

Aside from contusions, wounds of the chest may be of all types, and are inflicted by blunt objects, machinery accidents, explosions, knives, bullets, glass, spikes, nails, swordlike pieces of timber in saw mill accidents, and the bits of mine machines. Nonpenetrating wounds are not particularly grave. Hemorrhage is generally slight unless an intercostal, the internal mammary or a branch from the axilla is severed. Of course, they, as other wounds of the body, are subject to the dangers of infection. Muscles may be severed and nerves, especially the anterior and posterior thoracic, causing a paralysis of serratus and pectoral muscles. These should be sutured immediately.

The treatment is the same as in wounds of other parts of the body, control of hemorrhage, disinfection by iodin, removal of foreign bodies, sutures, if necessary, and drainage. Penetrating wounds of the chest may be of the most varying character, from the slightest perforation to the most severe lacerations by machinery. Their gravity depends on, first, the amount of hemorrhage, and, second, on the amount of air and especially of any foreign or septic material introduced. Penetrating injury of the heart demanding surgical treatment is most often the result of stab wounds.

Drainage in Surgery of the Chest

DR. GEORGE A. HENDON, Louisville: The means adopted for the accomplishment of drainage in a general way are careful hemostasis, accurate approximation and perfect asepsis. When these three objects are arranged the necessity for drainage no longer exists. They may be accomplished, first, by careful ligation of blood vessels; second, obliteration of dead spaces with the use of buried sutures and surgical cleanliness in the superlative degree. The first of these requirements is the easiest, the third is possible if contamination has not preceded the surgeon. The second (the obliteration of dead space) is the only one of the three which seems at the present time to be beyond the range of surgical possibility and occupies the most important consideration in chest surgery. To avoid the necessity of using a foreign body for the drainage of a space that cannot be obliterated the following measures may be adopted: Occupying the space by a medium in which micro-organisms will not grow, therefore eliminating the necessity of drainage.

Wounds and Injuries of the Rectum and Anorectal Region

DR. BERNARD ASMAN, Louisville: The clinical manifestations induced by anorectal wounds and injuries vary according to the instrument which inflicted the trauma, the extent of the damage to the tissues, the anatomic situation involved, the time which has elapsed between infliction of the injury and observation of the patient, and also the nature of the wound, i. e., whether contused, lacerated or perforating in character. The higher lesions are the most serious because of the likelihood of pelvic and abdominal complication. Contusions and lacerations are attended by less clinical danger than perforating and punctured wounds; the former are more likely to be superficial than the latter and adequate drainage can be more readily secured. The most dangerous type of injury is rectal or colonic rupture which permits the escape of blood, gas feces and pathogenic micro-organisms into the pelvic or abdominal cavity, the most logical result being the supervention of infection with the production of peritonitis, abscess, or fecal fistula. Even superficial wounds may result disastrously provided drainage is inadequate and infection with tissue sloughing ensues. However, if surgical treatment be instituted promptly and rigid asepsis maintained infection of clean wounds should not occur.

Where the surgeon has reason for believing the injury extends to the upper rectal segment, the sigmoid or colon, immediate celiotomy is indicated as a diagnostic measure, and at the same time to permit the necessary reparative procedures. The extent of the damage inflicted on the lower rectal segment and the anal canal may be easily determined by ocular inspection.

The treatment of anorectal wounds and injuries is primarily and essentially surgical, and the technic of reparative measures must be modified to meet the indications in each individual instance. The operative steps necessary will depend on the location, nature and extent of the damage inflicted.

7 Case of Congenital Anterior Subluxation of Tibia. L. Mayer, New York.—p. 521.
8 *Foot Prophylaxis in Soldier. J. T. Rugh.—p. 529.

1. System of Orthopedic Instruction.—The scheme Lovett presents can best be summarized by a concrete instance. The deformities of rickets can be taught in one of two ways: one is to describe knock-knee, its cause, mechanical production and treatment, and then do the same for bow legs and coxa vara, which is a good way and the usual one. The other way is to teach about bone, its growth and ossification, to tell of bone disturbances, the most frequent of which is a certain disturbance of ossification called rickets; that this process causes softening, and that bending thus occurs according to the mechanical influences in the case, perhaps in one direction, perhaps in another; that there may be an inward, outward or forward deformity of the leg; that ossification must be brought to normal by diet and hygiene; do not operate until this has happened. Meanwhile, treat by braces or manipulation. Thus one links up rickets with other disturbances of ossification, achondroplasia and the like. In the latter method Lovett believes that the man will have received more education than in the former.

4. Pathology of Peripheral Nerves in Gunshot Wounds.—Cone examined specimens from about 200 cases of war injuries of peripheral nerves. The patients were soldiers who, having had serious wounds by shell or bullet, in which soft parts and bone, as well as nerves, were torn or cut, came for repair of the nerves months after the original injury. The original wound had generally healed, yet it was considered advisable to wait until the lapse of six months after the injury before operating on the nerve; a few of the patients were brought to the operating table earlier, but many were not operated on for a year or more after injury. Many of the old healed sinuses suffer serious infection if operated on before the lapse of six months. In a few cases examination of material from the depths of the old wound shows masses of small round cells with few bacteria; some grow staphylococci on culture; others are negative. Many of the nerve trunks examined present masses of small round cells among the fibers; a few contain polymorphonuclear leukocytes. The vascularity is invariably greatly increased, new capillary vessels and full grown arteries and veins being found in all cases throughout the specimens. The fibrous scar between the nerve ends contains young nerves in 90 per cent. of cases. The increase of connective tissue is seen along the fibers some distance from the point of severance. Mixed with it is a proliferation of young nerves intertwining with capillary vessels among the old nerve fibers. This neuritis Weir Mitchell and Tinel say is often due to hemorrhage into the nerve.

Cone has never failed to find nerves in painful scars. The peripheral portion of a severed nerve contains axis cylinders in 86 per cent. of observations. The new connective tissue within, between and around injured nerves is most commonly wavy and vascular, often cellular, seldom dense. Nerve tendrils grow about foreign bodies such as khaki, hair and sutures. They grow well in granulation tissue. Fat is a better medium for nerve growth than is muscle. Nerves grow into fascia lata when used as a covering. Cargile membrane is impervious to nerve growth. A stretched nerve shows active growth of young tendrils. Circular constricting scars are particularly damaging. Young nerves grow wildly, most prolifically, and are hard to keep from growing. Pain may be caused by this great proliferation.

5. **Primary Suture in Treatment of War Fractures.**—Baer says that the primary suture is the method of selection in the treatment of these cases when this can be done. Experience has shown that primary suture may be performed successfully in 80 to 90 per cent. of the cases. In certain cases primary suture cannot be done, owing to the inability to make a closure due to the destruction of large amounts of tissue, including skin. But even here the primary suture at times may be accomplished by the aid of a skin flap. Technic of primary suture: Disinfection of skin with iodin, soap, water and a scrubbing, or other methods. Removal of skin edge, together with the tract made by the projectile. Removal of all projectiles and of all devitalized tissue. The securing of complete hemostasis. The accurate approximation of skin edge without tension. The time limit for primary suture is generally regarded as being within the first twelve hours, but in face cases the time limit for successful primary suture is slightly increased.

Ten per cent. of battle casualties, even when they have arrived at the hospital within the first twelve hours, cannot be closed primarily, and mainly for the following reasons: Cases in which the shock is so great that the patients cannot stand the operation within the first twelve hours; deep wounds, where the complete excision of all devitalized tissue is uncertain or impossible: wounds wherein no roentgenogram being present, the projectile cannot be extracted; wounds where the loss of substance is so great that complete closure is impossible, etc. Of the primary sutures, 5 to 10 per cent. are not successful, and this is due mainly to streptococcus.

In an evacuation hospital, all wounds which are received within the proper time after injury, and which are applicable to primary suture, are closed by this method. At the same time, cultures of the wounds are taken. The wounds that must be opened immediately on the bacteriologic report are those primarily infected with the virulent types of streptococci. A bacteriologic report of other organisms does not in the main disturb the surgeon. Mechanical sterilization by the operative procedure of primary suture, together with the action of the human tissue, takes care of all other organisms, particularly when in pure culture. The virulent streptococci, generally by themselves, and always when associated with other organisms, such as streptococcus, enterococcus, the gas gangrene group, etc., demand immediate opening of the primary suture. The delayed primary suture is the method of wound closure which has been adopted in all those cases in which primary suture would have been done except for circumstances, generally of military character, which made it inadvisable.

The technic of delayed primary suture is exactly that of primary suture, except that the skin is not closed, and a dry, sterile dressing is placed over the wound. The skin edge is brought together from three to eleven days later.

All primary sutures should be kept at the place of operation for at least ten days, so that the wound may be watched and not subjected to the traumatism in transportation. Therefore, where patients must be removed immediately, within six or seven hours after operation, delayed primary suture takes the place of primary suture. This method of procedure has been found eminently successful. The delayed primary sutures are sent to the rear within six or seven hours after the initial operation, and are closed preferably on the second, third or fourth day. The percentage of cures in delayed primary sutures is between 80 and 87 per cent. This method allows the beds at the front to be continuously utilized, and adds to the rapidity of recovery over the former methods. Baer urges the necessity for the early treatment of bone injuries, by primary or delayed primary suture, as this is the keynote to the successful handling of war fractures.

8. **Foot Prophylaxis in Soldier.**—Rugh states that if a careful foot examination were made by a competent orthopedic surgeon, when the soldier is first inducted into service and proper remedial measures outlined and instituted for such conditions, fully 90 per cent. of the foot inefficients could be eliminated. This plan, however, has not been feasible thus far. Four factors stand out in the solution of the problem of foot prophylaxis, each of them capable of thwarting all efforts and of preventing success. These four factors, in order of their importance are: (*a*) the feet, (*b*) the shoes, (*c*) the officers, and (*d*) the soldiers—though experience shows that they are of almost equal significance. (*a*) The feet present all types and conditions. (*b*) The shoe question has been solved by Colonel Munson, as 98 per cent. of the men's feet can be satisfactorily fitted with this shoe. (*c*) The officers in charge of the men are held responsible for the proper fitting of the shoes, instruction of the men in care of the feet, etc. (*d*) The man is the fourth factor in foot prophylaxis. His pride in his foot dress not infrequently makes him unwilling to wear the regulation shoe, and especially when a sufficiently large shoe is fitted to him. Again, whether he is an enlisted or drafted man influences very much his feeling toward possible foot disability. The one serves voluntarily in most cases, and the other involuntarily, and there very readily develops in the latter a mental state which exaggerates a slight ache or pain into an absolutely disabling condition.

From the orthopedic standpoint, the prophylactic measures that have proved most potent in foot prophylaxis are four: 1. The detection of the potentially weak cases. 2. One of the most important measures is the restoration of the balance to the foot by proper alteration of the shoe. 3. After training follows in the problem of reclamation, and the first essential is that of proper walking and standing. 4. Exercises for the restoration of muscle power are the follow-up for protection and corrective work in foot cases. Other prophylactic methods are to be used as they may be indicated and whenever opportunity offers, but after shoes have been properly fitted and altered, the above are probably the most important ones to use. First problem: Inspection of the feet of the new recruit should be accomplished in the casual detachment or the depot brigade, where he is first quartered on entering service. Second problem: When the recruit is transferred to a National Guard or Regular Army camp, he may be sent directly to his organization or to quarantine barracks. If to the latter, the feet should be inspected and proper remedial correction made before he reaches his final station, and proper entry of this correction should be made on his records, so that future change in shoes may also receive the same attention. Third problem: Intensive inspections, if done in a regiment, are always arranged for through the regimental surgeon, and through him with the regimental commander. There is practically no trouble in obtaining this if its purpose is explained to the colonel and major. Great care should also be used to interfere as little as possible with the ordinary work of the organization, and a regular schedule for the inspection should be made out and followed closely. After a little practice one can inspect from 150 to 175 men in an hour. Fourth problem: The installation of cobbling and alteration outfits. Fifth problem: The securing of cobblers for work in the camp repair shop. The most satisfactory results obtain from asking assignment of several men (preferably cobblers or shoemakers) from an organization for temporary duty in the camp shoe repair shop, and then to arrange for their instruction in shoe repair and alteration work. After six to eight weeks of work, they should be returned to their organization and several sent from other units to take their place for similar instruction. During this time these men have been working efficiently in the shop, have learned the trade for practical purposes, and are still a part of their original organization, and are available for cobbling work in overseas service. Commanders will allow temporary assignment but not transfer, and when the economic phase is placed before the commanding general or chief of staff, they readily cooperate. Sixth problem: The care of cases of foot disability should rest with the regimental surgeon. Seventh problem: Experience in camp work quickly shows the orthopedic surgeon that he must work out his own problems and allow others to do the same.

13 Radical Cure of Hernia under Local Anesthesia; Combined with Scopolamin and Morphin. J. H. Cunningham, Jr., Boston.—p. 336.

9. **Diagnosis of Fracture of Hip.**—Given these three symptoms—disability, eversion of foot and pain on manipulation—Gay says, that the diagnosis is reasonably certain in all injuries to the hip. The older the victims, the more reliance can be placed on them. Shortening of the injured limb is almost always present, but it is less readily determined than are the above mentioned cardinal symptoms. Slight shortening, that is, not exceeding half an inch, is not always detected, especially in stout persons. In some cases only an expert can detect any difference in the length of the limbs. While unmistakable shortening is a valuable symptom of fracture of the hip, yet it is not as readily detected as are other conditions. Crepitus is usually absent in impacted fractures, depending of course, on the degree of impaction. This symptom is not to be sought too curiously. The manipulations should be gentle and intelligent. The diagnosis can be made satisfactorily without this symptom. Other comparative symptoms of hip fractures are Nélaton's and Bryant's lines, designed to show the relative elevations of the top of the great trochanters on the two sides. The comparative tension of the fascia lata above the trochanters is also a sign of some significance. The only dislocation of the hip that presents the same, or a similar clinical picture as a fracture, is the displacement forward. This dislocation is so extremely uncommon that most physicians have never seen a case. The most common errors in diagnosis in hip injuries are in calling them sprains and contusions.

37. **Tuberculosis, Osseous and Glandular, Treated with Tuberculin, Contrasted with Cases Treated Without Tuberculin.**—With a few exceptions these patients were children, inmates of a home for crippled children and patients in a hospital clinic. Without tuberculin 16 recovered, or 32 per cent.; 25 died, or 50 per cent.; 9 are still wearing braces and under treatment, or 18 per cent. With tuberculin 33 recovered, or 66 per cent.; 5 much improved, or 10 per cent.; 6 died, or 12 per cent.; 5 still under treatment, or 10 per cent.; 1 discontinued treatment, or 2 per cent. Of the 16 cured without tuberculin the average period treatment for each case was five and a fourth years. Of the 33 cures with tuberculin the average period of treatment for each case was eleven and a half months. Of the 25 deaths without tuberculin the whole period of treatment was seventy-two years, eleven months, nine days, or three years, fourteen days for each patient. Of the 6 deaths of those treated with tuberculin the total period of treatment was four years, nine months, and twenty-nine days, or an average of nine months, thirteen days for each patient. Of those treated without tuberculin, 9 are still under treatment. Of those treated with tuberculin 5 are still under treatment.

54 Character as Integral Mentality Function. G. G. Fernald.—p. 448.

46. **Care of Military Insane.**—Does Army life make men insane? The question is especially important in a warfare which involves the whole nation as bearing on the economic value of psychiatric examinations. Bailey says that so far as epilepsy and mental deficiency are concerned, the present statistics do not throw much light. While camp conditions might easily, and as a matter of fact often do, give rise to nervous episodes in the mentally deficient, they have nothing to do with the underlying cause. The same may be said of epilepsy. The frequency of attacks in epileptics may be increased after entering the Army, but figures so far obtained do not justify the assumption that a potential epileptic under peace conditions is converted into an actual one by Army life. But the matter is quite different with the psychoneuroses, constitutional psychopathic states and dementia praecox. It seems that even in the training camps any of these conditions may become active and conspicuous through the requirements of military service when they had not manifested themselves

to a degree to be incapacitating in civil life. It is not believed that this conversion of a potential psychosis into an actual one in the camps is a result of hardship or physical causes. It is believed rather to be a psychologic result from disharmony with new and rigid conditions which the neurotic, who is so intensely individualistic, finds it impossible to adapt himself to and so breaks down. This explanation holds true for those who have volunteered quite as much as for those who have been drafted.

So far as the expeditionary forces are concerned, the time has not yet come to explain the method of production of psychoses. Most of the wounded so far returned had departed for France before the neuropsychiatric examinations had been established. Among them there is a percentage of nervous and mental disease of twenty-five, a percentage that seems destined to decrease as the figures more and more concern the examined Army. Experience indicates that a pronounced psychopathic constitution and military service are antagonistic. It is believed, on the other hand, that psychoneurotics who might render excellent service in their civil capacity, become incapacitated by the change in their habits of living however patriotically they may have sought it. It is also believed that the Army fares better without them.

49. **Mental Disease in the Field.**—Harrington was regimental officer with the British Expeditionary Force in France for a year, he had an opportunity to see a fairly large number of mental and nervous cases; and although, unlike physicians serving in base hospitals, he had no opportunity to make a careful study of his cases, he had a better opportunity to observe the conditions under which they developed and the practical problems which they presented to the military organization. Harrington is convinced that in the cases resulting from war strain there is little if anything that is really new. Emotional shock, fatigue, etc., the various etiologic factors which give rise to war psychoses, are all found operating in civil life; and as for the psychoses themselves, there is probably nothing in their symptomatology that cannot be duplicated in the ordinary psychiatric clinic of any large city. The difference between peace conditions and war conditions and the mental disturbances resulting from each, is not a qualitative difference, but a quantitative one. Under peace conditions, for example, men are subjected to emotional shocks in no way essentially different from those produced by shell fire. But under peace conditions these shocks are of rather rare occurrence, and as a rule so mild as to affect only those who are mentally unstable. Under war conditions, however, they are of constant occurrence, and frequently so severe as to affect the strongest and best balanced of men. Thus etiologic factors and types of mental disorder to which formerly little attention was given have, with the altered conditions produced by the war suddenly forced attention; and as a result there has been a tendency to treat of them as if they were something altogether new.

69. **New Dressing for Wounds.**—The material used by Kahn for an internal dressing or drain and for an external absorptive dressing, either wet or dry, is blotting paper prepared in a variety of ways; and as an external binder to take the place of the cloth roll or bandage, punctured paper adhesive on one side for binding it over the dressing or wound. This adhesive roll last mentioned can be variously medicated and used over surfaces much as ordinary adhesive plaster or mustard plaster. The wound is prepared for dressing much as any wound is prepared, the difference being that instead of using gauze and cotton as a drain, Kahn uses blotting paper, corrugated, thin, and in strips, as a drain; and blotting paper crumpled up in the hand as an external dressing. The blotting paper may be reinforced with a little gauze, or with a cloth roll bandage over the blotting paper, or a binder of the corrugated, punctured, adhesive paper may be used. The paper dressing makes a light, airy and inexpensive dressing, it is easily removed, and is more readily destroyed than a cloth dressing.

77. **Food Value of Candy.**—Candy being composed principally of sugar, chocolate and nuts, is very high in food value, and the different kinds vary in the proportion of carbohydrates, fat and protein they contain. Sugar is highly concentrated food. Sugar is easily digested. On account of the rapidity with which it is assimilated, sugar quickly relieves fatigue. Six ounces of sugar are equal in food to 1 quart of milk, or 1¼ pounds of lean beef. It has a fuel value of 1,810 calories. Nuts are very high in food value, those used principally in manufacturing confectionery being almonds, filberts, pecans, peanuts and walnuts, averaging approximately 1,500 calories per pound. Corn syrup, erroneously called glucose, used largely in manufacturing gum drops, hard candies and taffies, is a pure wholesome transparent heavy syrup, manufactured from corn. The food value as expressed in scientific terms is 1,559 calories per pound.

Candy is composed of various raw materials of high food value; it is, therefore, apparent that candy being composed of combinations of two or more of these raw materials is exceptionally high in food value. With but three exceptions, the different kinds of candies are very much higher in fuel value than whole milk having a fuel value of only 315 calories per pound, cream 881 calories, whole eggs 695 calories, beefsteak 1,090 calories, corn 1,685 calories, rice 1,620 calories, white bread 1,180 calories, and corn bread 1,175 calories. The high nutritive value of chocolate candy is recognized by the leading military authorities of the world, and the "boys at the front" are satisfying their craving for "something sweet" with chocolate cakes and tablets and candies of various kinds. Scientists have demonstrated by careful experiments that during violent exercise or exhausting labor, the sugar in the blood is very heavily drawn on to supply the body with the necessary fuel, hence the longing for "something sweet" which can be readily assimilated, and which is most easily and conveniently supplied in some form of candy. The Swiss guides for mountain climbers consider lump sugar and sweet chocolate an indispensable part of their outfit. Children should have candy frequently. It is better to give them candy frequently than to give only occasionally, when the craving for it creates an almost irresistible temptation to overeat. It is especially desirable that candy should be served for dessert. A moderate amount frequently is better than an occasional overindulgence.

3. **Bladder Injury in Warfare.**—Fullerton says that injuries of the bladder form a very small proportion of the total wounds reaching the base hospitals, one in 3,000 or 4,000. Their importance from the point of view of prognosis and treatment depends to a large extent on associated injuries. In the present series 35, or nearly 70 per cent., were complicated by injury to intestine or bone, or both. In 26 cases there was a wound of some part of the lower intestinal tract, and 13 of these were also complicated by osseous fracture. There were 19 cases of damage to the rectum. In 6 cases the small intestine was wounded. In 22 cases there was damage to the bones of the pelvic girdle. The pubic bone was fractured in 12 cases, once in association with the sacrum, once with the great trochanter, and once with the head of the femur, involving the hip joint. The sacrum was fractured in 5 cases; once in association with the pubic bone. The iliac bone was factured in 2 cases; once in association with the ischium. The ischium alone was fractured in one case. In 2 cases the coccyx was fractured. Damage to the prostate was present in 7 cases. The anterior crural nerve was injured in 1 case, the sciatic nerve in 2 cases, the femoral vein in 1 case, and the spine (concussion) in 1 case; involvement of the spermatic cord, necessitating orchidectomy, was present in 2 cases. According to Fullerton, the importance of the perivesical connective tissue cannot be overestimated. This forms a potential, continuous space extending from the cavum Retzii in front, round the sides of the bladder and rectum, to the posterior part of the latter behind. Pelvic cellulitis is a frequent complication.

The mortality of bladder injuries is very high, 13 deaths (over 24 per cent. in this series). In cases reaching the base it may be estimated at 30 per cent. The chief causes of death have been pelvic cellulitis, peritonitis, and sepsis. The chief sequelae are necrosis of bone, persistence of cystitis, calculus, and stricture at the neck of the bladder.

Fullerton points out that the treatment should be conducted on common sense lines. Accumulations of infected fluid, blood clot, and fecal material in the pelvic connective tissue must if possible be prevented by attention to the original wounds. If this is unsuccessful, suitably planned incisions should be made. The fact that urine flows over the surface of a wound is not necessarily in itself an indication for suprapubic cystostomy. If the bladder can be kept clean by irrigation, aseptic urine from the kidney does not appear to have a deleterious effect on the wound. Suprapubic cystostomy will drain an infected bladder, but will not prevent pelvic cellulitis and sepsis from occurring in the perivesical connective tissue and parietes, respectively. The after-treatment of the bladder by frequent irrigation is necessary to get rid of cystitis and prevent calculus formation.

7. Suture of Gunshot Wounds.—Of the 303 cases entered on the research list, primary or subsequent suture of the wounds was actually carried out in 285. Three patients died, a mortality of about 1 per cent. Comparison of results of the use of antiseptics showed that among 41 cases of primary suture, primary union (complete or partial) occurred in 37 with failures in 4 cases. With a few exceptions, only the slighter wounds have been treated without antiseptics, and this may account for the results without antiseptics being the best (90 per cent. of successes). As regards immediate suture, flavine and ether come next (86 and 84 per cent. of successes), then soap and bismuth iodoform petrolatum paste (about 76 per cent.).

Regarding delayed suture, the figures, so far as they go, show a decided superiority over the results given by immediate suture. Of 224 wounds sutured primarily, cultures were made in 215. Of the latter, 21 were negative; all these healed completely by first intention. The remaining 194 were infected with anaerobes, streptococci, or other organisms mentioned in the bacteriologists' report. In the 194 infected wounds treated by immediate suture, anaerobes occurred in 119, nonhemolytic streptococci in 62, hemolytic streptococci in 20 and other organisms in 95.

The general conclusion drawn from these figures by the committee is that wounds infected by the hemolytic streptococcus nearly always become septic, while a large proportion of wounds infected in other ways healed by first intention. Failure took place in only one case of primary suture which was infected by anaerobes alone; in this case a muscle flap used for filling a bone cavity sloughed and a gaseous abscess developed in the wound. Only one case infected by hemolytic streptococci (a small wound penetrating the knee joint without damage to bone) healed by first intention; all the rest suppurated, many of them violently and with severe constitutional disturbance. Infections by nonhemolytic streptococci as a general rule appear to be less virulent. When failure occurs, the suppuration is usually milder than that characteristic of the hemolytic streptococcus. Sometimes, however, the nonhemolytic streptococcus, in association with other organisms, appears to set up sepsis of a very severe type.

The advantage which delayed suture offers as compared with immediate suture depends on the knowledge of virulent infection gained during the interval while the wound is open. Even if a bacteriologic examination has not been made, the appearance of a virulently infected wound when first dressed, forty-eight or seventy-two hours after operation, is usually distinctive, and it is not sutured. In this way the proportion of failures after delayed suture should be reduced to a very small percentage. While no antiseptic tried by the committee either in open or closed wounds, appears to have any appreciable effect on the growth of the hemolytic streptococcus, the results of the use of flavine point to the probability that chemical antiseptics, when applied to the surface of open wounds infected with bacteria of less virulence, may fulfil a useful function.

It was found advisable to discontinue the use of flavine solution after four or five days, as wounds treated continuously with this substance for longer periods tend to become covered with a layer of coagulated lymph or necrosed tissue in which bacterial growth appears to flourish. Used in the early stages for a limited time, flavine gives satisfactory results.

The committee found that the narrow track of a bullet which has passed into or through a limb, without producing an explosive effect by spinning or striking a bone, is usually sterile, and that operation on wounds of this type is unnecessary. Further, they found that where the entry wound and part of the track are clean and narrow, while the exit is lacerated, only the exit wound is likely to be infected. In such a case operation should be limited to a careful cleansing of the exit wound, damaged tissue being removed only till the orifice of the narrow track is exposed. A culture taken by introducing a swab into the latter will probably be negative, and this part of the wound need not be interfered with.

British Medical Journal, London

Aug. 17, 1918, **2**, No. 3007

14 *Ischemic Myositis. J. P. Stewart.—p. 151.
15 *Cases of Subacute Bacterial Endocarditis. H. J. Starling.—p. 154.
16 Attempt to Breed Tubercle Immune Cattle. L. J. Picton.—p. 157.
17 *Modification of Stokes-Gritti Amputation. W. A. Chapple.—p. 158.
18 *An Acid-Fast Bacillus Obtained from Pustular Eruption. L. Cobbett.—p. 158.

14. Ischemic Myositis.—Stewart advises treating this class of case by means of a careful and systematic stretching of the shortened tissues as recommended by Sir Robert Jones.

15. Subacute Bacterial Endocarditis.—Starling reports five cases. Particular attention is directed to certain symptoms. 1. Ephemeral spots of painful nodular erythema which were noted in two cases and had recurred for some months (at least six months in one case) before admission to the hospital. The patients paid less attention to the spots than to the fact that their finger-tips were on occasions tender when handling anything. Two patients stated that some days after all the tenderness and swelling had disappeared they were able to pick the so-called scab off the fingers. In one case a node appeared on the pinna of the left ear. 2. Petechiae were seen in all the cases in varying degrees and at different times. In two cases they occurred in showers, being scattered freely over the chest, abdomen and thighs. 3. Splenic enlargement was present in all the patients on or soon after admission to this hospital. The degree of enlargement varied with and in each case. 4. In no case was the pyrexia severe. 5. In four cases was demonstrated the occurrence of arterial embolism in a degree which is most unusual and worthy of record: (1) at the bifurcation of the left brachial artery; (2) at a branch of one of the left retinal arteries; (3) (*a*) in the right radial artery at the wrist; (*b*) in the left popliteal artery in the bend of the knee joint; (*c*) in a branch of the left suprascapular artery; (4) (*a*) in the left femoral artery; (*b*) in the left posterior tibial artery, in both instances before admission to this hospital; (*c*) at the junction of the right axillary and brachial arteries. 6. Hematuria was not marked in any of these cases.

17. Modification of Stokes-Gritti Amputation.—Chapple cuts the quadriceps attachment to the upper edge of the patella completely across, and then stitches the margins of the patella with catgut to the edge of the periosteum round the end of the femur. One or two additional deep catgut sutures will usually be sufficient, and a firm button suture through the skin flaps will make assurance doubly sure.

18. Acid-Fast Bacillus Obtained from Pustular Eruption.—The bacillus was cultivated by Cobbett from chronic intractable pustules covering the back, buttocks, and thigh of a soldier returned from France. No micro-organisms were seen in the pus, and none could, at first, be cultivated from it. But subsequently there was grown, on more than one occasion, an acid-fast bacillus which is the subject of this note.

25 *Treatment of Malignant Malaria in East Africa. M. Roche.—p. 165.

25. **Treatment of Malaria in East Africa.**—African malignant malaria has been completely eradicated quickly and easily by means of intramuscular injections of quinin spread over a month. Sixty grains of quinin bihydrochlorid were given by eight injections, each of 7½ grains. Roche says that about 80 per cent. of cases of cerebral malaria can be cured by quinin if it is energetically injected into the muscles and the rectum. The remaining cases are usually both unconscious on admission and of fatal termination.

28 Differential Diagnosis of Dysenteries. J. G. Willmore and C. H. Shearman.—p. 200.
29 Recent Epidemic of Smallpox in Field. G. H. Mead.—p. 206.

27. **Treatment of Shell Shock.**—In two series of 1,000 cases each Brown treated 173 in the first, and 132 in the second by means of hypnosis. In these two series there were altogether 121 cases of loss of speech, or hysterical mutism. He succeeded in curing every single one of these cases. Many of the patients were deaf as well as dumb. These were given a paper of instructions to read, in which they were told to lie down, close their eyes, and give themselves up to sleep. When such a patient showed by the calm look on his face that he had reached a quiet frame of mind, Brown would suddenly and unexpectedly bang two books together near him, and have the pleasure of seeing his eyes flicker, and then find that he could hear. Brown could then continue the treatment by word of mouth in the ordinary way.

Brown is convinced that the essential therapeutic agent in the case of hysteria caused by shell shock is "abreaction," or the working off of the repressed emotion caused by the shock. Mental analysis is a means to this end, and light hypnosis, applied under proper safeguards, is the quickest and most effective method of effecting this analysis, in cases in which amnesia is present and the patient is seen early. For cases of neurasthenia, which are the more numerous and involve emotional preoccupation often dating back many years, mental analysis and reeducation, without hypnosis in any form, are the needful agents, although the abreaction of the original emotional disturbance or disturbances is again essential. In both classes of cases the arousing of sthenic emotion in the patient's mind is an important adjunct in the cure, both in the form of enthusiastic confidence in his physician and expectation of a complete recovery, and also in the form of vivid interest in some form of occupation in the stage of convalescence, during which the mind becomes more unified and consolidated.

Rest, is, of course, also fundamental. But no complete rest is possible while the mind is obsessed with bottled-up emotion. This emotion must be completely worked off, and then true rest will come. The preoccupations of the neurasthenic also must first be dealt with if any form of rest cure is to produce good results. After three and a half years of work with nerve patients in military hospitals in Egypt, England and France, during which over 4,000 cases have passed through his hands, Brown feels no hesitation in saying that mental analysis is the ideal method of treatment, provided that it is carried far enough to produce true abreaction of emotional states.

32 *Early Recognition of Feeblemindedness and Other Forms of Social Inefficiency. R. J. A. Berry and S. D. Porteus.—p. 87.
33 Treatment of Bone and Joint Wounds. L. G. Teece.—p. 91.

32. **Early Recognition of Feeblemindedness.**—As the result of a prolonged research, Berry and Porteus publish what they believe is a practical method for the early recognition of feeblemindedness and other forms of social inefficiency: (1) The person's brain capacity is first ascertained, and is compared with the percentile brain capacity of the population. This examination is supplemented by physical and psychophysical tests proved to have diagnostic significance. (2) A psychologic examination is then carried out as thoroughly as possible. The authors do not depend on the application of any single set of intelligence tests, but on a combination of methods. (3) Finally, the whole examination is correlated with the clinical, personal, family and educational history of the person, and the results interpreted in the light of the person's social environment.

The hypothesis on which the authors base their work is, that, as mental development is conditioned by brain capacity, striking deviation from the normal in brain size will tend to be associated with mental abnormality. In order to determine the cubic capacity of brain of a normal living boy or girl, at different ages of their educational career, the authors examined some 10,000 children and university students, with control cases drawn from known abnormal sources. Next the range of variation from the mean was determined and how far, if at all, extremes in this range were to be regarded as abnormal. For the former Berry and Porteus have employed the standard deviation and other well known statistical methods of mathematical science. For the latter they made use of Sir Francis Galton's method of percentiles, and the standard deviation as a unit of possible abnormality.

A table of percentiles was constructed from the results of these findings. Certain facts of importance in the early recognition of feeblemindedness and other forms of social inefficiency are clearly revealed. These are: (1) That head measurement alone is, and must always be, an uncertain guide as a measure of intellect or its lack. (2) That, as mental development is entirely dependent on brain matter, striking deviation from the normal in brain size tends to be associated with mental abnormality. (3) That when this deviation attains a certain sufficiently high degree, it must be revealed by head measurement and the calculation therefrom of brain size. (4) That such cases of striking deviation are due, in many instances, to developmental failure of the outer, supragranular, or "intellectual" layer of the cerebral cortex, and as this necessarily means a greatly diminished number of myelinated neurones, there will be a smaller sized brain, which head measurement, even in its present imperfect stage, is capable of detecting. Hence, small headedness will be of more diagnostic significance than large headedness. (5) That the authors' percentile tables of brain capacity are distinct aids to the diagnosis of mental inefficiency, and afford a more certain basis for the psychologist to work on than has hitherto been the case, because they afford some clue to the relative development of the supragranular (educational) and infragranular (instinctive) layers of the cortex cerebri of the person.

35 Heart Block with Transient Changes in the Ventricle Beat. P. D. White (Boston).—p. 352.
36 Heart Disease and Fitness for Service. J. Heitz.—p. 355.

34. **Malignant Endocarditis.**—Vaquez discusses the acute, subacute and protracted forms of vegetative endocarditis, saying that only the acute form is primary; the others are generally grafted on some old valvular lesion. The name *Streptococcus viridans* applied to the microbe of the protracted type is not a good one, as the green tint that surrounds the cultures is not a constant phenomenon, and there seems to be no reason for thus distinguishing the streptococcus of malignant endocarditis. In seven of his nine personal cases he found the streptococcus in the blood, but in the two others only the pneumococcus was found.

June, 1918, **71**, No. 6

37 *Kinetic Plastics and Prostheses. M. Stassen.—p. 657; Theory. J. Vanghetti.—p. 663; Technic. Pellegrini.—p. 675.
38 *Kinetic Amputation. S. Pieri.—p. 688.
39 *Meningeal Reactions of Syphilis. B. Dujardin.—p. 706.
40 *War Neuropsychiatry. H. Hoven.—p. 721.

37. **Kinetic Plastics.**—The principle of adapting the stump after amputations to utilize all the muscular force left in the various muscles and tendons has been repeatedly described in these columns. A series of articles here describe the principle and technic for the plastic operations and likewise for the amputations, with examples of the various types and the results realized in motor functioning. Pellegrini lines the tunnel through the muscle by rolling into a tube a horizontal transverse strip of skin left attached at both ends. The tube thus formed is the bar over which the tendons or muscles are sutured to form a loop. The skin around is then sutured to cover the whole except at the attached ends of the skin tube. A steel hook coated with celluloid is run through the skin tube, and thus the motor force in the tendon or muscle loop can be imparted directly to the steel hook and from this to the prosthesis. A man amputated in the forearm is shown holding a pail, a valise, a carafe, and writing with the artificial hand, all under motor control. The whole kinetic operation can be done at one sitting.

38. **Amputations for Kinetic Prostheses.**—Pieri emphasizes the necessity for bearing the later kinetic plastics in mind when amputating. The best motor functioning is realized with the free loop; for the forearm, a double loop, one for extension and one for flexion. An ample supply of sound skin is of the greatest importance not only to line the tunnels but also to cover the outside of the loop, the portion most exposed to trauma. His illustrations show the technic for the various amputations to fulfil these conditions. The *Archives* thus brings the whole subject of kinetic plastics down to date, with twenty-five illustrations.

39. **Meningeal Reactions in Syphilis.**—Dujardin has had occasion to do lumbar puncture on a large number of syphilitics before, during and after treatment. For about two weeks after the syphilitic chancre no appreciable reaction in the cerebrospinal fluid is apparent. Then as the spirochetes enter the blood, the sensitive meninges respond to the irritation with slight lymphocytosis while the skin shows as yet no sign of irritation. As the septicemia progresses, the spirochetes proliferate in the skin foci. Not until several weeks later do they proliferate in the meninges; by this time the organism has become relatively immunized against the spirochete, and this explains the comparative mildness of the meningeal and nervous phenomena. The ephemeral character and the fluctuations in this immunization explain the play of subsequent recurrences. For instance, arsenical treatment destroying the more accessible skin foci, puts an end to the vaccination, and if the arsenical treatment is stopped too soon, the result may be renewed proliferation of the spirochetes in the meningeal foci. An inadequate course of arsenical treatment may thus entail a violent meningeal reaction. On the other hand, nothing is more encouraging than to watch the effect on the meningeal reactions of a properly conducted course of arsenical treatment.

40. **Shell Concussion.**—Hoven says in the conclusion of his review of the present status of war neuropsychiatry, that the prognosis of organic nervous disturbances from shell concussion is grave; their evolution is always long. But all the other disturbances rapidly subside.

43 Chloroma. J. Comby.—p. 427.

41. **Desquamating Erythrodermia in Infants.**—Comby has encountered generalized exfoliating dermatitis in thirty newborn infants in the last few years. They were usually well developed and no defects in hygiene could be incriminated in the majority. It develops early, never later than two months, but it has certain analogies with the eczema rubrum of older children. The epidermis drops off in large flakes as with scarlet fever or burns of the second degree. There are no grave general symptoms, no blistering or suppuration unless ill advised medication induces irritation. Seborrhea of the scalp generally accompanies it and persists after it. Under dry powdering the dermatitis soon subsides.

42. **General Paresis with Inherited Syphilis.**—Sousa's patient is a boy of 7 who was apparently healthy till the age of 5.

46 Three-Day Fever on Hospital Ship. P. Joly and Baril.—p. 138.
47 *Serum Treatment of Epizootic Lymphangitis. P. Latour.—p. 141.

44. **Shell Concussion.**—Dupré concludes his study of the *syndrome commotionel* by emphasizing the analogy between its symptoms, from the initial unconsciousness to the tardy changes in character and in the capacity for resistance and effort, and the symptoms to which we are accustomed with an apoplectic stroke. The latter may be regarded as a *syndrome commotionel* of internal origin, while the shell shock is the result of similar sudden disturbance in the circulation of external origin. The physical commotion induces apoplectic coma, while an emotional shock sets in play the defensive motor reactions of the instinct of self preservation, but repeated emotional shocks may lead to nervous exhaustion by a kind of emotive anaphylaxis. A violent shell concussion as well as an intense emotional stress may lead to a grave psychopathic condition of delirious nature, chronic and tending to dementia. In several instances he has witnessed a catatonic or hebephrenic psychosis, characteristic and incurable, develop at once after a shell concussion or after intense emotional stress.

45. **Automatic Regulator for Irrigation.**—Daure interposes in the supply tube a reservoir which automatically tips up when a certain amount of fluid has dripped into it. When the reservoir contains the desired amount (gaged with precision) it tips over and pours the fluid into the tube below. The contrivance was devised for Carrel treatment, which is now being applied to mastoid cases, but it may prove useful also in other fields.

47. **Epizootic Lymphangitis.**—Latour relates that great ravages are being caused among the army horses by contagious lymphangitis imported by the African contingents. No treatment proved effectual until the serum from convalescent horses was administered by subcutaneous injection. The results were excellent, he says, in the twenty-eight horses given this treatment. Some of the horses were given daily injections of 10 or 20 c.c. but the best results were obtained with massive doses, 100 c.c., at four or five day intervals. The second injection was followed by marked improvement and the cure was complete as a rule after the fourth or fifth. Twenty-four of the twenty-eight horses resumed their service in from three to six weeks, while with all other treatment the disease dragged along for three or four months.

48 *Lethargic Encephalitis. Alfred-Khoury.—p. 455.
49 *Primary Poliomesocephalitis with Narcolepsy. De Saint-Martin and J. Lhermitte.—p. 457.
50 Febrile Nervous Form of Epidemic Influenza. A. Chauffard.—p. 462.
51 *Orchi-Epididymitis. G. Faroy.—p. 465.
52 Oculomotor Reflex with Orbital Tumor. Rouquier.—p. 467.

48. **Lethargic Encephalitis.**—Khoury reports a case in a man of 55, distinguished by attacks of jacksonian epilepsy. The somnolency was the only symptom for a week, then came fever, bilateral ptosis, strabismus, retention of urine, and convulsions on one side. The urine and spinal fluid seemed approximately normal till death the twenty-third day. In the discussion that followed, four similar cases were mentioned, all of recent date, the fever not appearing for a week or ten days.

49. **Primary Poliomesocephalitis with Narcolepsy.**—De Saint-Martin and Lhermitte report two cases in which headache and invincible somnolence for a few days were followed by diplopia and ptosis. The bilateral paralysis of the third pair was complete, involving not only the external ocular muscles

but the musculature of the iris, with paralysis of accommodation and the light reflex, but no signs of involvement of other nerves or the cerebellum. They define the cases as primary superior polioencephalitis, and regard them as the same disease which Chauffard and others have been reporting and calling lethargic encephalitis. They think this name should be reserved for sleeping sickness. In the district in central France where they encountered the two cases reported, an epizootic is prevailing among poultry almost in endemic form.

51. **Orchi-Epididymitis.**—In one of the two cases described the orchi-epididymitis developed during convalescence from mild colon bacillus sepsis and in the other during convalescence from typhoid. It proved transient in the first case, but has persisted in the other during the nine years to date.

Journal de Chirurgie, Paris

June, 1918, **14**, No. 5

53 *War Wounds of Vessels. J. Okinczyc.—p. 441.
54 *Appendicostomy in Treatment of Acute Dysentery. G. Cotte.—p. 465.

53. **War Wounds of Blood Vessels.**—Okinczyc discusses the immediate hemorrhages and diffuse hematomas, the secondary hemorrhages and the tardy disturbances in the form of aneurysms. Among 220 wounded, 24.7 per cent. had one or more large blood vessels injured. When they do not bleed at once, the injury is liable to be overlooked, and he emphasizes the importance of seeking involvement of the vessels in war wounds as a routine practice. The traject of the projectile, roentgenoscopy revealing a projectile near a vessel, and spontaneous or induced pain in the course of a vessel are all instructive. This pain localized in the wounded vessel, sometimes extending to the whole limb, is the more remarkable, he says, because war wounds, aside from fractures, are generally only slightly painful at first. One man, for instance, had eight or ten wounds on the legs, buttocks and lumbar region. The left thigh seemed to have escaped as there was no trace of a projectile having entered. But the man complained of pain in this thigh alone, pointing to a spot over the femoral artery. On the basis of this pain, Okinczyc cut down to the artery and found that it had been grazed by a projectile on its way downward, and there was thrombosis for 2 cm. The discouraging frequency of gangrene after ligatures has compelled him to look about for other procedures.

54. **Appendicostomy in Dysentery.**—Cotte has applied this method of treatment in five grave cases of acute dysentery, and the results were so fine that he thinks it deserves wide adoption. He cut off the appendix, leaving only enough of a stump to hold the catheter. The cecum was fastened with four silk stitches to the parietal peritoneum. The latter was sutured except for the catheter. General anesthesia is necessary; in the one case done under local anesthesia, the cecum and colon had slipped entirely out of sight and could not be found without manipulations which the debilitated patient would have been unable to stand. Cotte used always a 1 per thousand solution of silver nitrate, repeating the lavage every day or second day until the stools were formed.

55 *Experimental Study of Healing of Nerves. J. Nageotte.—p. 245.
56 The Circulatory Disturbances in Shock. H. Delaunay.—p. 293.
57 *Lumbar Puncture in War Surgery. F. Albert.—p. 328.

55. **The Healing of a Severed Nerve.**—Nageotte's account of his extensive experimental research is profusely illustrated. Among the conclusions is the statement that the interposition of a nerve graft—in dogs—aids in the regeneration so that healing may proceed perfectly, with complete restoration of function. The nerve graft was kept in alcohol (50 degrees). The young nerve fibers are attracted into narrow interstices, and this stereotropism is favored by providing the regenerating nerve with a graft of easily permeable tissue, with longitudinal interstices. A graft from a rabbit nerve is best adapted for the purpose, but as this is so small, he preferred a nerve graft from a calf fetus. This dead heteroplastic nerve graft gave perfect results in some of the dogs. He thinks that these findings might apply to human beings, but the graft would have to be made early. In old wounds, changes in the stumps of the nerves would render any intervention futile.

57. **Lumbar Puncture with Skull Wounds.**—Albert expatiates on the advantages of lumbar puncture in surgery of the skull. It differentiates simple meningeal irritation from local compression of the cortex, and simple hernia of the brain from hernia caused by an inflammatory process below. With the latter, the hernia does not collapse even after repeated lumbar puncture. The latter is indicated in treatment of concussion of the brain, fracture of the base of the skull, and for all cases of irritation of the cortex with increased secretion. He reiterates that when the condition is not improved by lumbar puncture, some serious injury may be assumed, calling for craniectomy. Among the fifteen cases described to illustrate the benefit in these various conditions, are four of post-traumatic meningitis.

62 Traumatic Cerebral Hemorrhage. Chavigny.—p. 28.
63 Discharge for Insanity in Soldiers. R. Benon.—p. 29.

58. **Headache After Shell Concussion.**—Mairet and Piéron call attention to symptoms indicating irritation of the trigeminal nerve after a shell concussion. There probably are minute suffusions of blood responsible for the irritation. The latter induces headache and tenderness along the nerve, and this sign of trigemino-occipital irritation is objective testimony to the concussion. Pressure on the emerging point of the nerve, especially above the orbit, causes pain which spreads to the back of the head, along the course of the great occipital nerve.

64. **The Streptococcus in War Wounds.**—Plisson, Ramond and Pernet remark that streptococcus war wounds constitute at present an entirely new morbid entity, as they are set apart from all other war wounds, primary suture being forbidden them. The course of sixty-seven war wounds containing streptococci is reviewed here. They all are in chains and take the Gram, but otherwise they differ so widely that it is always a question as to the unity or plurality of streptococci, but all forms seem to be equally dangerous in war wounds. They induce an infection like an actual erysipelas of the walls of the wound, against which the organism vaccinates itself only slowly and tardily. It takes weeks for a streptococcus wound to heal up, but a fatal termination is exceptional. After the danger of gas gangrene is past, the prognosis is not grave for the man himself, but it is grave for the state, as he is kept suppurating for months, and the army thus loses his services. No method of disinfection to date has proved effectual against the streptococcus, but the progress of the wound can be hastened by secondary operative measures, Thiersch flaps or exsection, as for a tumor, of a wall of tissue, including the whole of the wound and 2 or 3 mm. beyond its edges and its bottom, which one avoids touching during the operation; strict hemostasis; primary suture with filiform drainage at each end. These secondary operations were never done before the third week, by which time the organism had evidently acquired a certain amount of immunity in respect to the streptococcus. No antiserums or colloidal metals, etc., ever displayed any efficacy; the reliance must be

on the organism itself to accomplish its own vaccination. Prophylaxis is the main thing. Segregation of all the streptococcus cases is important, but the best guarantee against streptococcus infection is the early and minute *épluchage* of the wounds.

66. **Serotherapy and the Myth of Anaphylaxis from It.**—Summarized, August 17, p. 605, when published elsewhere.

67. **Tardy Effects of Concussion.**—Léri refers to cases in which the focal lesions in the nerve centers from the concussion from a shell explosion did not develop until several days or weeks afterward. By that time the connection with the shell concussion is apt to be overlooked or unrecognized, and the nervous disturbance, paralysis, hemiplegia, etc., are liable to be mistaken for hysterotraumatism, etc. Among the various types of these *commotions retardées* are the forms with generalized muscular atrophy, aphasia, hemiplegia or amyotrophic paralysis of the quadriplegic type. The prognosis of these tardy manifestations seems to be far more favorable than for those that develop at once. Nearly all the men whose stories are related had recovered more or less completely in the course of a few months to a year. The fact that these organic lesions in the spinal cord or brain may not reveal themselves for several days or weeks or months is important from the medicomilitary standpoint. The acquired fragility of the vessels in the brain and spinal cord of men who have suffered a concussion of this kind should be borne in mind in the estimation of focal lesions which develop later. Léri adds that the question of *amyotrophies post-commotionelles* has not been brought up before. The very slow and progressive development of the muscular atrophy has prevented its real cause from being discovered.

68. **Mixed Anesthesia.**—Pellot has devised an apparatus with which 15 parts ethyl chlorid are given with 3 parts of ether and 2 parts of chloroform; 20 c.c. of the mixture insures complete anesthesia for twenty minutes. He claims for it all the advantages of pure ethyl chlorid with none of its disadvantages.

69. **Resection of Hip Joint.**—Chutro describes with illustrations a method of operating in case of grave infection of a war wound of the hip. The oblique osteotomy of the neck of the femur permits good drainage while retaining the upper surface of the neck its entire length; and retaining the capsular muff intact. The wound is drained with six or eight Carrel tubes. In his nine cases the whole intervention took only ten minutes, and the hip joint was left functionally capable with an average shortening of only 3 cm.

70. **Action of Epinephrin on Digestive Tract.**—Binet's review of the literature demonstrates that epinephrin has an undoubted modifying action on the vascularization, secretion and motor functioning of the digestive tract. Introduced directly into the stomach, epinephrin does not seem to display any toxic action. But introduced into the rectum, it proves very toxic in doses similar to those that are lethal for the animals when injected subcutaneously. He ascribes this to the close anastomoses between the hemorrhoidal veins and the portal vein, the liver being apparently the barrier which arrests the epinephrin ingested. Neither pepsin nor trypsin nor passage through intestinal capillaries seems to alter the epinephrin ingested. On the other hand, digestive disturbances from suprarenal insufficiency are known. These and other data learned from experimental research are useful, he says, to guide the physician. They are instructively supplemented by Grasset's case in which 35 gm. of 1 per thousand solution of epinephrin was swallowed with suicidal intent, without appreciable results.

72 *The Influenza Epidemic. R. Staehelin.—p. 1057.
73 Present Status of Tuberculosis. O. Amrein.—p. 1060.
74 Cancer Statistics. Labhardt.—p. 1066; J. Aebly.—p. 1069.
75 *The Osmotic Pressure in the Serum in Typhoid. A. E. Alder.—p. 1072.

72. **The Influenza Epidemic.**—Staehelin writes from Basel that the prevailing epidemic resembles in every respect the pandemic of influenza in 1889 only that it is apparently more malignant. The influenza bacilli have been cultivated from blood and sputum in different localities, and pneumonia seems to be a frequent manifestation; forty-six of the 309 cases in his service in about six weeks terminated fatally. Leukopeny seems to be constant in the more serious cases, and an eruption resembling that of scarlet fever is common. He isolates the sick as for diphtheria, and there has been no ward contagion but two of the attending physicians, seven nurses and four attendants in contact with the sick have had the disease. The salicylates reduced the temperature temporarily and camphor proved useful in pneumonia, especially with venesection when the latter was indicated.

75. **Freezing Point of Blood Serum in Diagnosis of Typhoid.**—Alder investigated the osmotic pressure in the blood serum of twelve typhoid patients and tabulates these and the metabolic findings, as also in four other patients whose disease proved not to be typhoid. In 75 per cent. of the typhoid cases the osmotic pressure in the serum was found decidedly reduced at the very beginning and through the height of the disease. In the others it fluctuated. He suggests that this early reduction in the osmotic pressure as shown by the freezing point may prove useful in the very early differential diagnosis of typhoid.

Annali di Ostetricia e Ginecologia, Milan

February, 1917, **19**, No. 2, Pub'd, August

76 *Obstetric Ureter-Bladder-Vaginal Fistulas. A. Bertino.—p. 41.
77 *Pregnancy Chorea. S. Flamma.—p. 69.

76. **Obstetric Lacerations.**—Bertino reports a case in which there was both a vesicovaginal fistula and a fistula between ureter and vagina. The latter was not discovered until the persisting drizzling of urine after the first fistula had been corrected led to its discovery. Both fistulas were evidently the result of simultaneous injury during delivery at term with a moderately contracted pelvis, probably when the fetal head was being rotated. A functional cure was realized by implanting the ureter in the bladder wall by an extraperitoneal technic.

77. **Pregnancy Chorea.**—Flamma's patient was a woman of 21 and the chorea developed at the third month of her first pregnancy. The chorea growing worse was accepted as an indication to arrest the pregnancy, after which it gradually subsided. Becoming pregnant a year later the choreic movements recurred, commencing in the second month. The woman and her husband begged to have abortion done as the choreic movements were incessant and severe. Convinced that the trouble was principally of nervous origin, a sham obstetric intervention under chloroform anesthesia convinced the couple that the abortion had been done, and the chorea rapidly and completely disappeared. As the pregnancy approached term and the couple realized that their wishes for a child were to be gratified without the woman's suffering from the chorea, they were very much pleased. Flamma reviews the literature on chorea gravidarum. Chorea in childhood, hysteria, a fright or an inherited neurotic taint are frequently mentioned in the antecedents, but in some cases no factor could be incriminated except the pregnancy. He remarks that pregnancy chorea and chorea in the pregnant are not necessarily the same thing. The mortality of pregnancy chorea is given as 8.3 per cent. in one of the latest compilations. Sham interruption of the pregnancy proved effectual also in another case in the clinic in which the psychogenous manifestations took the form of incoercible vomiting. These twin cases with the same origin but different manifestations, cured by the same measure, confirm the conception of a psychogenous origin. Before inducing actual abortion in dubious cases of the kind, a sham intervention may answer the purpose.

78 *Tuberculin Test in Measles. O. Cozzolino.—p. 449.
79 *Partial Wet Nursing. A. Borrino.—p. 457.
80 Torpor of Blood-Producing Organs. G. Milio.—p. 467.

78. **The Tuberculin Reactions in Measles.**—The veering from positive to negative in the response to the tuberculin

test during measles is ascribed by Cozzolino to the changes in the skin induced by the eruption.

79. **Supplementary Wet Nursing.**—Borrino refers to cases in which the mother's milk is absolutely inadequate or the breast is deformed, or the mother is severely ill. Under these conditions, instead of resorting to artificial feeding, she advocates securing the services of a woman living at home and nursing her own child, who will give the breast to the infant a few times during the day. Four typical cases are described in which very sick infants were thus tided along in good condition until the mother could nurse them adequately herself.

86 *Early Operations for War Wounds. G. Pisano.—p. 525.

82. **Iodoform Treatment of Tuberculous Pleuritis and Peritonitis.**—Maurizi reports excellent results from injection of a suspension of 2 or 4 gm. of iodoform in 10 or 20 gm. liquid petrolatum in treatment of tuberculous pleuritis. The iodin released slowly from the suspension kills the tubercle bacilli, and this in turn generates what amounts to an autotuberculin, while the absorption of the effusion is a kind of autoserotherapy. He begins with an exploratory puncture but does not remove the effusion unless it is in excessive amounts. There may be a febrile reaction which reaches its height next day and lasts from five to seven days. Generally one injection answers the purpose. He keeps the patient on milk exclusively as long as the reaction is apparent. Surgical treatment is necessary with staphylococcus or streptococcus empyema, but it is contraindicated for the tuberculous. It does not cure the primary process while it is liable to set up associated infection and entail an incurable fistula. Capparoni uses glycerin instead of liquid petrolatum, but Maurizi found the glycerin too irritating.

86. **Operating in Advanced Stations.**—Pisano recommends a small portable barrack with equipment for surgical work, which can be packed complete in two trucks and set up close to the front wherever needed. He has long been advocating operations close to the firing line to spare the wounded the strain of transportation.

90 Appendicitis and Life Insurance. I. Romanelli.—p. 245.
91 Xylol in Treatment of Tuberculosis. G. Volpino, Colombino and Fornaroli.—p. 253.

87. **Fracture of Neck of Femur.**—Ghillini calls attention to the fact that as the patient with fractured femur reclines, the weight of the shaft drags down the distal stump of the neck so that it lies below the plane of the proximal stump. This of course prevents exact coaptation of the stump ends. It can be avoided, he says, by bracing the pelvis against some support, and then having the limb straightened by traction on the foot and leg. Measure the distance on the sound side from the anterior superior iliac spine to the greater trochanter, and the distance betwen these points on the side of the fracture. An assistant then, with one hand under the buttocks on the side of the fracture, raises the greater trochanter until the distance between it and the iliac spine measures the same as on the sound side. A strip of plaster is then applied passing from one side to the other of the thigh and leg, and made to adhere to the limb with strips of gauze. Then a cement and plaster cast is applied, enclosing the pelvis and reaching from the umbilicus to the knee. The assistant holds the limb in inward rotation while the plaster is hardening, which brings the fragments together. In his first case he worked under roentgen control, but found this superfluous, as the measurements alone answered every purpose. He applies extension by Volkmann's method, with a 5 or 10 kg. weight, keeping the stirrup fastened to the foot in inward rotation. The limb is thus immobilized for about fifty days. The fracture by this means heals in the correct anatomic relations. The only drawbacks with the method he found to be that others accused him of faking the roentgenograms of his cases, as no one would believe that such complete restoration of a fractured femur was possible. He reproduces four of them.

89. **Osteoporosis After War Wounds.**—Guarini relates how the roentgen rays showing osteoporosis after industrial accidents and war wounds have freed many persons from the stigma of simulation, as they revealed trophic changes in the bone responsible for the patient's complaints. The trouble may commence in from four weeks to four months after the injury. Osteoporosis is especially frequent after war wounds, and the early detection of the tendency is important from several standpoints. He suggests that the demineralization should be combated by dietetic measures, first making sure of normal conditions in the digestive tract. In some cases, organotherapy might also be considered. Electrotherapy and physical measures may improve the circulation in the limb and promote the nourishment of the periosteum and joint cartilage. Nineteen cases are described in detail, with illustrations. In one woman the lumbar spine was the seat of constant pains and tenderness, first explained by the osteoporosis revealed by the roentgen rays. Trophoneurotic influences after a war wound were evidently responsible in some cases. Guarini found a tendency to osteoporosis in from 25 to 50 per cent. of 3,500 roentgen examinations of the wounded. It was frequent in the small bones of the hand or foot after war wounds not far above, and in the elbow. Inflammation is evidently a factor, but long immobilization of the limb certainly cooperates.

92 *Convulsions in Infants. C. Francioni.—p. 393.

92. **Convulsions in Infants.**—Francioni found that some of the infants under 3 months old who had convulsions developed afterward normally, some traumatic or circulatory disturbance from the birth process evidently having been responsible for the convulsions. In others, symptoms of spasmophilia became manifest later, or of inherited syphilis or of tuberculosis. Whatever the etiology, the convulsions were alike in all. It is manifest further that digestive disturbances may aid in bringing on convulsions with an inherited taint or from other cause, but the stage of the development of the nervous system evidently cooperates, before the third month and after the eighth month being the periods of greatest frequency of convulsions.

95 Pyrexias at Caracas. F. A. Risquez.—p. 128.

94. **Chaulmoogra Oil in Tuberculosis.**—Hernandez found that addition of 2 per cent. chaulmoogra oil to the culture medium always prevented development of tubercle bacilli. His experiments with it in guinea-pigs also seemed to confirm its destructive action on these bacilli. He gave small injections of the oil to six tuberculous patients. The best results were obtained with injection of not more than 1 or 2 c.c. at twenty or thirty days' interval. Under this all the symptoms subsided in some of the cases. In the discussion that followed, Rincones suggested that possibly this oil might render the waxy shell of the bacillus less resistant, so that then it might yield to serotherapy.

107 Tubal Embryoma. S. Ohno and H. Takaoka.—p. 24.

105. **Artificially Induced Tumors in Mice.**—Tsutsui applied to 259 mice Yamagiwa's method of inducing malignant proliferation of tissues by repeatedly painting them with coal tar. Only sixty-seven of the mice survived to the hundredth day, the others succumbing probably to intoxication from the tar as they licked the spot. A tumor developed in thirty-five of the sixty-seven surviving, that is, in 52 per cent. The microscope showed on continued application of the tar, carcinoma in sixteen and sarcoma in one of the animals, an average of 23.8 per cent. of the animals that lived more than 100 days. There is some chemical substance in the tar, he thinks, which must be incriminated in the development of the carcinomas, but mechanical injury must not be left out of account, as the spot of the application is often bitten by the animal, and there is further repeated irritation as the scar is lifted up for renewed painting with the tar.

106. **Transplantation of Fowl Tumors.**—Among the points brought out by Yamamoto's experiments with fifty-eight strains of fowl tumors and one of dog and of guinea-pig tumors, is that the arrest in the growth of a tumor and the resorption of an already completely developed tumor, and the failures in transplantation, must stand in some intimate connection with the sexual function of the animal in question.

110 Organization of Specialists. A. C. Van Bruggen.—p. 1784.

108. **Sulphemoglobinemia.**—Van den Bergh over ten years ago called attention to the presence of sulphemoglobin in the red corpuscles in certain cases. In a case recently encountered, the sulphemoglobinemia followed puerperal fever after a criminal abortion. The symptoms corresponded to those accompanying sepsis from anaerobic microbes. The skin turned a yellow or coppery color, while the nose, the fingers and toes and the mucosa looked blue. The scanty urine contained hemoglobin. Some of the women have recovered, but as a rule they die in a few days. The organs are found brownish, but the most striking finding is the apparent integrity of the sexual organs and peritoneum. In the case reported, the spectroscope showed lines typical for sulphemoglobin. It is possible that this has been mistaken for methemoglobin in some of the cases on record labeled methemoglobinemia. Methemoglobin is an ordinary derivative of hemoglobin, but sulphemoglobin is formed exclusively under the action of sulphuretted hydrogen. The discovery of sulphemoglobin in the blood will turn the scale in favor of sepsis rather than an intoxication. No one has succeeded in cultivating microbes from the blood in these cases. In the present case they had probably entered by way of the internal genitals but had not caused any local lesions. Proliferating in the blood, they attacked the hemoglobin.

111 *Exophthalmic Goiter in Children. H. C. Gram.—p. 913.
112 *Micro-Tests for Iron. M. Claudius.—p. 930.
113 Present Status of Pyelography. F. Rydgaard.—p. 937. Cont'n.

111. **Exophthalmic Goiter in Children.**—Gram cites the literature on this subject, and especially in reference to the unusual growth in height in children with exophthalmic goiter. This disease is rare in children. Sattler could find records of only 184 children under 15 in 3,477 cases of exophthalmic goiter on record. At the same time it is not infrequent to encounter in girls approaching puberty some slight enlargement of the thyroid with mild nervous manifestations and tendency to tachycardia—evidently a pathologic exaggeration of the physiologic hyperthyroidism at this time. Holmgren in 1906 called attention to the excessive growth which occurs in these conditions. The growth seems to be whipped up, and the bones settle prematurely into a condition which normally would occur only four or five years later. The epiphyses become consolidated, so that growth has to cease after this spurt, the children not being exceptionally tall when they reach their majority. Gram here reports in detail three typical cases. The girls were harmoniously developed, with menstruation at 12. At 13, they were 13.5 and 10 cm. taller than the average for their age. There were no signs of acromegaly, unless this extra growth may be regarded as a lengthwise acromegaly.

112. **Micro-Tests for Iron.**—Claudius gives the details of a colorimetric and a titration micromethod for determination of iron in the blood or other fluid. The first is based on the transformation of the iron into soluble Berlin blue; the other on the combination of an iron oxid with soluble Berlin blue to form insoluble Berlin blue. An aqueous solution of Berlin blue is used for the color standard. The tint is proportional to the iron content; probably because the stain is a colloidal solution. Other colorimetric technics in vogue are unreliable as the stain becomes dissociated more and more into its colorless elements. This does not occur with a stain in colloidal solution. He comments on the importance of an exact micromethod for iron not only for chemistry in general but for clinical medicine. Only 0.10 c.c. of blood is required for either technic.

THE LYMPHATICS OF THE DENTAL REGION *

FREDERICK B. NOYES, B.A., D.D.S.
AND
KAETHE W. DEWEY, M.D.
CHICAGO

In place of the usual review of the progress of dental science and art, in the year past, which is given in a chairman's address, your chairman has decided to present a report of the work done in the Histological Laboratory of the College of Dentistry of the University of Illinois in the last three years. Two years ago, at the Detroit session, the first of this work was reported to this section.

First, I want to say that the technical work has been done by Dr. Dewey, in my laboratory, and she has prepared the review of the literature.

THE LYMPHATIC SYSTEM

Schweitzer[1] deserves the credit of first demonstrating, by injection, the presence of lymphatic vessels in the dental pulp and peridental membrane. Our work has corroborated his results, and filled out some of the gaps in his findings, especially in showing through its entire extent the drainage from the dental pulp, and the course of the vessels in the infra-orbital and inferior dental canals.

To those who are not familiar with this field of work, it may be well to say a word in regard to the character of the lymphatic system. All the cells of the body are bathed in fluid with which, through metabolism, they are in vital reaction. This fluid passes out through the walls of the blood capillaries into intercellular or interfibrous spaces, from which it is collected into minute canals, or spaces, lined by endothelial cells. These are known as the lymph capillaries. From these the fluid passes into larger channels with delicate endothelial walls, and finally into large lymphatic trunks, some of which have walls similar to the veins. The fluid is finally returned to the blood circulation through a valve-guarded opening into the subclavian vein. Along the course of these channels are interposed many lymphatic glands or lymph nodes.

As a general statement, lymphatic vessels are present wherever connective tissue is found. As long ago as 1891, Foster[2] said, "Of all the varied functions of connective tissue perhaps the most important is this relation to the lymphatic system; in nearly every part of the body connective tissue serves as the bed or origin of lymphatic vessels." Failure to inject them cannot be taken as proof that lymphatic vessels do not exist in a given location. Because of their inaccessibility and the structural peculiarities of the tissues, the dental system has long resisted all attempts to demonstrate the presence of lymphatic vessels.

The difficulty of injecting lymph vessels, as compared with blood vessels, can be readily appreciated. In some places large lymph vessels can be found, and because of the rich, plexus-like anastomosis of the small channels, they can be injected backward. In the dental region, however, this is quite impossible because of their minute size and the delicacy of the walls.

In the dental region, the method employed consists in slowly and gently carrying the fluid into intercellular and interfibrous spaces and by careful massage, forcing it through the interlacing, plexiform channels. In this way the injecting fluid is made to follow the natural course of drainage of the area, and to a limited extent can be forced backward into the other lymph capillaries. If this is kept in mind, it will be easier to interpret the illustrations.

LYMPHATIC VESSELS OF DENTAL SYSTEM

I will now describe briefly the arrangement of the lymphatic vessels of the dental system as made out by previous workers and as shown in our work.

Sappey[3] describes and beautifully illustrates the lymphatic vessels of the mucous membrane of the mouth, cheeks and lips. He shows a very rich plexus of lymph capillaries in every connective tissue papilla of the mucosa. These are drained into a rich delicate network in the submucosa, passing downward over the buccal and lingual surfaces of the alveolar process, and at the reflection from the bone to the cheek, or the bone to the tongue, forming a wreathlike network. In the lower jaw, this wreathlike network is drained by a few efferent trunks: on the outside, passing from the median portion to a submental lymph node and from the lateral portion to the submaxillary and superficial cervical nodes; on the lingual side, near the median line a few efferent trunks pierce the floor of the mouth and pass to the submental node. At the posterior portion they anastomose with the vessels from the sides of the tongue and the pharynx and pass chiefly to the median nodes of the upper group of deep cervical nodes.

In the upper jaw the wreath lying between the maxilla and the reflection of the cheek is drained by a

* Because of lack of space, this article is abbreviated in The Journal. The complete article appears in the Transactions of the Section and in the author's reprints. A copy of the latter will be sent by the author on receipt of a stamped addressed envelop.

[1] Schweitzer: Ueber die Lymphgefässe des Zahnfleisches und der Zähne beim Menschen und bei Säugetieren, Arch. f. mikr. Anat., 1907, 69, 207; 1909, 74, 927.

[2] Foster, Sir Michael: A Text-Book of Physiology.

[3] Sappey: Anatomie, physiologie, pathologie des vaisseaux lymphatiques considérés chez l'homme et les vertébrés, Paris, 1874.

few efferent vessels, most of which follow the facial vessels and reach the larger submaxillary nodes. On the lingual they run across the hard and soft palate and to the upper nodes of the deep cervical group, usually of the same side but anastomosing and often crossing to those of the opposite side.

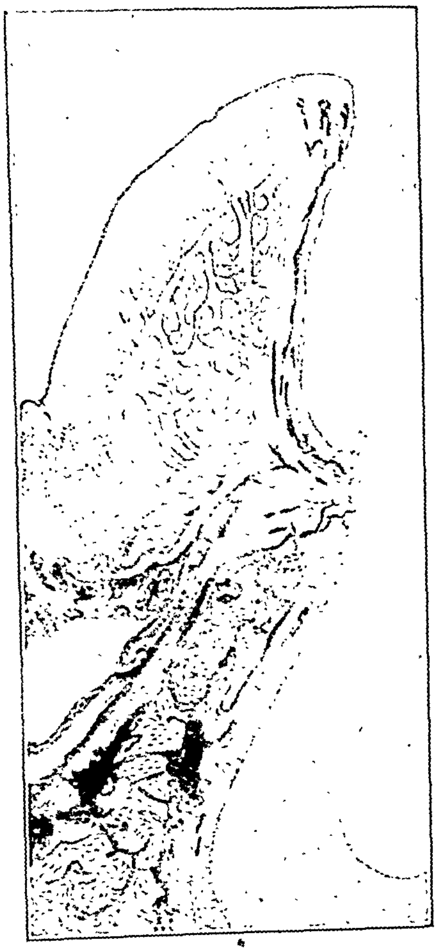

Fig. 1.—Unstained section, showing lymph capillaries of the tooth side of the gingivae and their drainage through the ligamentum circulare to the peridental membrane.

Sappey's description is confined, as far as the peridental membrane is concerned, to vessels lying to the occlusal of the ligamentum circulare.

I want now to emphasize the difference in the course of the lymphatic vessels from the papillae of the buccal and lingual slopes of the gingivae, as compared with the course of those from the long, slender papillae of the subgingival space (the side next to the tooth). As Sappey describes, the former do not penetrate the ligamentum circulare but pass down along the periosteum and to the wreathlike network at the reflection of the lip and cheek. The latter penetrate the ligamentum circulare and extend toward the apex of the root in the peridental membrane. Figure 1 shows the lymphatic capillaries of the papillae of the subgingival space, passing among the fibers of the peridental membrane close to the cementum, penetrating the ligamentum circulare and into the larger vessels coursing toward the apex of the root in the peridental membrane.

Figure 1 was drawn with the camera lucida from an unstained section. The results of this injection, as shown by this and other sections and as made out from careful dissection, may be described as follows: The needle was inserted under the periosteum well down on the side of the alveolar process, and the fluid slowly injected, with careful massage during and after injection. It will be seen that a lake was formed on the outside of the process from which the lymphatic vessels have carried the fluid through the spaces of the bone into the vessels of the peridental membrane. These have been filled in both directions, the fluid passing in them, occlusally and toward the apex. Occlusally it has passed through the minute vessels even into the ends of the papillae of the subgingival space. Passing apically, comparatively large vessels can be seen, as well as many small ones. Figures 2 and 3 were drawn from transverse sections of similar injections.

The connective tissue accompanying the blood vessels and nerves is seen to contain many injected lymphatic vessels. These continually anastomose with vessels in the spaces of the bone. At the apex of the root the vessels anastomose with lymphatic vessels which accompany the blood vessels through the foramina in the cementum into the dental pulp. Figure 4, which is cut transversely just at the apex of the root, shows one vessel passing from the pulp to the peridental membrane, and several cut transversely in other foramina. On reaching the pulp chamber, the lymphatic vessels are either perivascular or independent. The material seems to show that most of the larger blood vessels in the central portion of the pulp have perivascular lymph sheaths; but there are also good sized lymphatic vessels lined by endothelial cells independent of blood vessels. The latter seem to be chiefly toward the periphery of the pulp.

Figure 5 was drawn from a thick, unstained section. The injecting fluid has been forced out through lymph vessels into intercellular spaces in the pulp, and seems to be surrounding the odontoblasts. The coloring matter has even been dissolved into the dentinal tubules in some places. From this area small vessels may be seen uniting into a larger vessel. Several of these sections seem to indicate that the intercellular lymph spaces communicate with the dentinal tubules, and in this the experimental evidence corresponds with the clinical experience of discoloration of the dentin by the solution of blood pigments being carried into the dentinal tubules in infarction of the dental pulp.

The lymph vessels from the dental pulp pass through the apical space into the spaces of the bone, anastomosing with the rich lymphatic network in this tissue. The vessels pass to the periosteum, but drain to the inferior dental canal in the lower jaw and the infraorbital canal in the upper jaw. Here they form a rich plexus around the blood vessels and in the sheaths of the nerve trunks. Figures 6 and 7 are photomicrographs of these areas and show these vessels well injected.

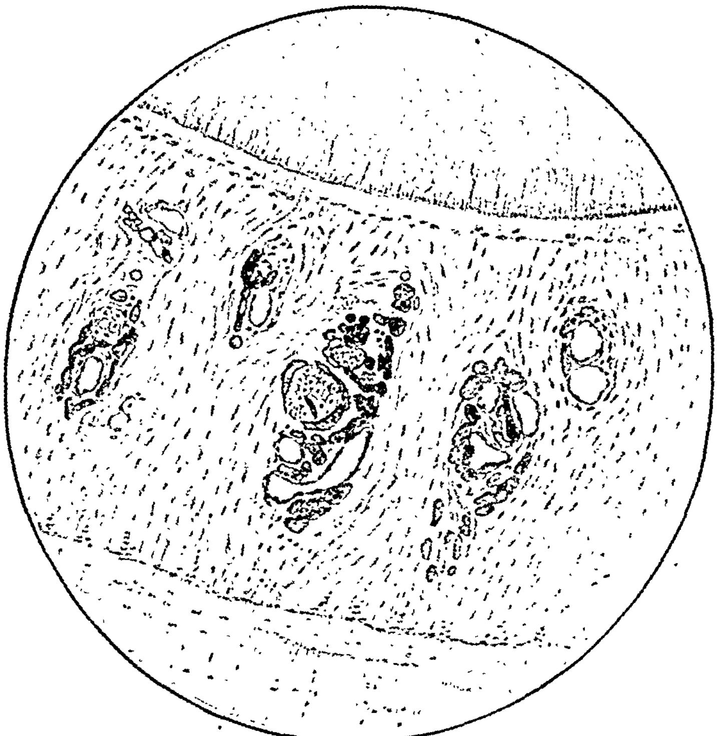

Fig. 3.—Transverse section of the peridental membrane, showing injected lymphatic vessels (oc., 3; obj., 16 mm.; reduced about one tenth).

The vessels pass out of the mental and infraorbital foramina, pass in a superficial course, and follow the facial artery and vein passing to the large submaxillary lymph nodes. Figures 8 and 9 are drawings of a head in which the vessels could be followed all the way from these foramina to the glands. In this head the only injections were into the pulps of the canines and first molars. Microscopic sections of the glands from similar specimens showed the injecting material to be in the lymph spaces of the glands.

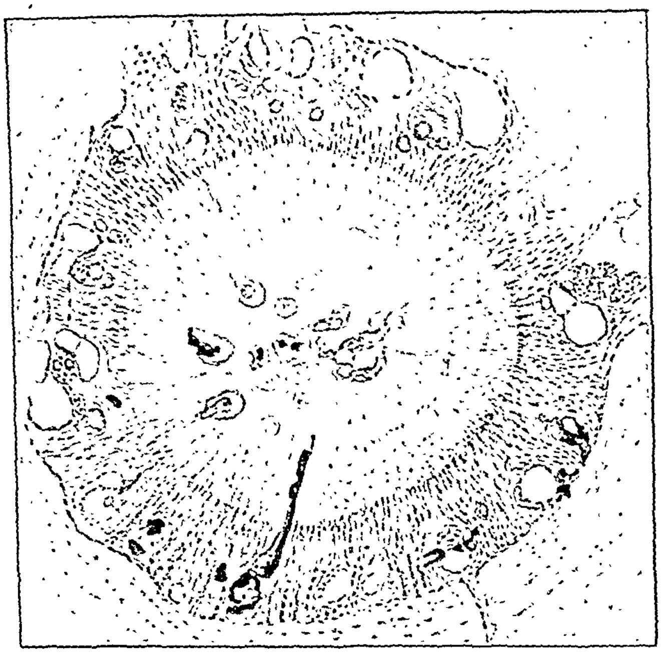

Fig. 4.—Transverse section just at the apex of the root, showing injected lymphatic vessels in the peridental membrane and in the canals passing to the pulp (oc., 2; obj., 16 mm.; reduced about one third).

Our work supplements that of Schweitzer in two important ways: first, in showing the injection of the lymphatic vessels in the inferior dental and infra-orbital canals, and so showing the complete course of drainage to the submaxillary nodes; and second, in showing the same course by injections only into the pulps of the teeth.

Subperiosteal injection of the lymphatics is especially interesting in reference to infiltration anesthesia, and the course of lymphatic drainage from the papillae of the subgingival spaces is especially important with reference to the progress of destructive inflammation of the peridental membrane.

REVIEW OF LITERATURE AND TECHNIC

The only report in literature of successful injection of the lymphatic vessels of the peridental membrane is one by Schweitzer,[1] who was also the first to demonstrate the presence of lymph vessels in the dental pulp. Other references about lymph vessels in the peridental membrane are limited to mere suggestions and the assumption that they may exist. Ebner[4] describes as structures belonging to the lymph system reticular meshes filled with lymphoid cells, which may be found embedded within the dense fibrous tissue about the teeth. Black[5] referred to nests of nucleated cells in the peridental membrane near the cementum as "lymphatic" glands. In later publications he modified this view to the effect that these cell collections may be glandular structures. Dorendorf,[6] who made a study of the lymphatic circulation of the lip with reference to the spread of carcinoma, extended his experiments to injections of the lymph vessels of the gingiva and the periosteum, but only brief protocols of the results of the injections are given, because, as he states himself, complete specimens could not be obtained.

The lymphatics of the gingiva are better known. Sappey[7] gives a clear picture of the arrangement of the lymph system in the gingiva and the palate, but fails to refer to any lymph vessels in the peridental membrane, while he mentions unsuccesssful attempts to demonstrate lymph vessels in the dental pulp and does not hesitate, in spite of failures, to express his belief that they may exist.

The older method of injecting lymph vessels with mercury which has yielded excellent results in such skilful hands as Sappey's, has been largely superseded by methods employing less heavy injection masses, and it is most likely due to the greater power of penetration of the more fluid masses that lymph vessels could be demonstrated which failed by mercury injection methods. The mass in most common use now is the so-called Gerota mass, Prussian blue or Berlin blue in the oil color, dissolved in turpentine oil and sulphuric ether. With this mass and a method known as the Gerota method, Schweitzer was able to inject successfully the lymph system of the peridental membrane and to a less complete degree lymph vessels of the dental pulp. The general picture of the lymphatic arrangement in the peridental membrane, as Schweitzer expresses it, is that of a funnel extending from the deepest layers of the gingiva down into the alveolus. The walls of this funnel lying in the peridental membrane consist of a dense network of lymph capillaries in several layers, anastomosing with one another. The main trunks, which arise from this network and which are larger than the blood vessels, run in a direction longitudinal to the axis of the tooth. They communicate with one another by numerous anastomoses. At the level of the ligamentum circulare,

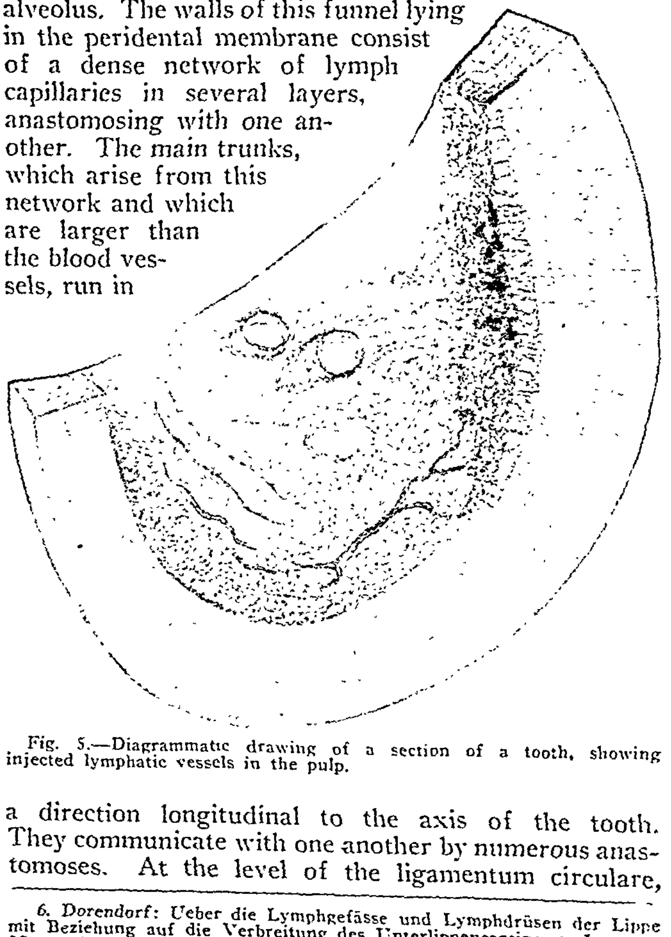

Fig. 5.—Diagrammatic drawing of a section of a tooth, showing injected lymphatic vessels in the pulp.

[6] *Dorendorf*: Ueber die Lymphgefässe und Lymphdrüsen der Lippe mit Beziehung auf die Verbreitung des Unterlippencarcinoms, Internat. Monatschr. f. Anat. u. Phys., 1900, **17**, 201.

[7] Sappey (Footnote 3), p. 69.

lymph vessels are present in several rows which surround the tooth like a wreath. The vessels ascending from this assume the form of lacunae and round masses, which in sections have the appearance of bunches of grapes. Numerous anastomoses connect the lymph vessels of the peridental membrane, first, with the neighboring larger lymph vessels passing through the bone; secondly, at the inlet of the alveolus with the deep lymphatic network of the gingival submucosa, and thirdly, at the apex of the root with the lymph vessels accompanying the larger blood vessels entering and leaving the dental pulp and therefore also with the lymph paths of this organ. In the lower jaw they communicate also with the lymph vessels which follow the blood vessels and nerves within the mandibular canal.

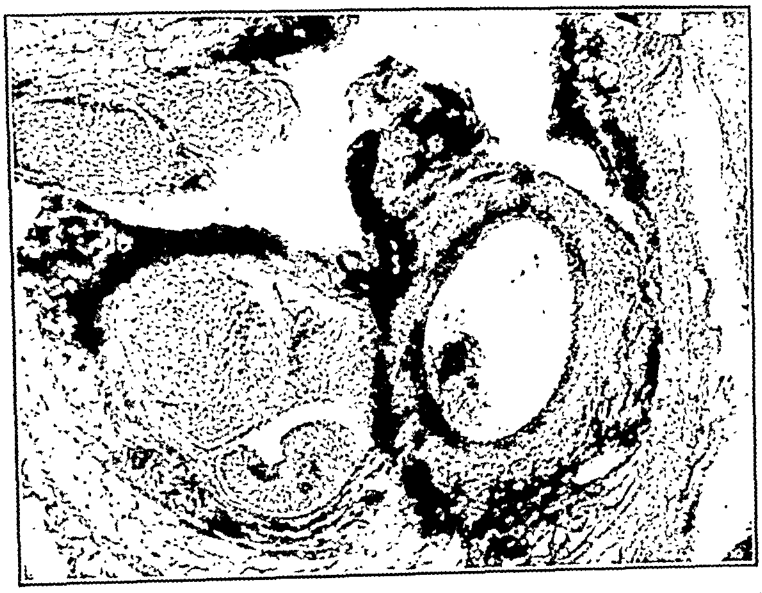

Fig. 6.—Photomicrograph, showing injection of perivascular and perineural lymph spaces in the vessels of the inferior dental canal.

The lymph vessels of the gingiva have been successfully injected by several investigators. Sappey was the first to demonstrate them, and the accuracy of his statements has been, in the main, verified by the results of later workers. After having described the lymphatic apparatus of the gingiva, he expresses the view that one should expect the dental bulbs, which are actually nothing else than papillae of the mucous membrane, to be provided with lymph vessels like all other papillae of the integuments. In fact, in spite of his failures to inject them, in the adult, the child and the fetus, he is still inclined to believe in their existence. According to Sappey, the vessels of the gingiva passing between the teeth unite into one vessel on either side on each jaw, and in the region of the last molar pass down into the deeper tissue. Most[8] admits the efferent vessels apparently are relatively scanty in number, but he believes that they are more numerous than Sappey claims; their demonstration by injections is difficult because the lymph capillaries in this region are extremely delicate, conforming to Teichmann's law that (so-called) lymph capillaries decrease in size and width the more delicate the mucosa is and the more the latter adheres to the subjacent tissue. Most was generally able to inject one, two and three trunks.

An interesting exception to another general principle laid down by Teichmann, known as Teichmann's rule, has been observed by Schweitzer to occur exclusively in the gingiva. According to this rule, the last terminals of the lymphatic apparatus always lie deeper, that is, more centrally than the blood capillary network. In the gingivae we find the reversed condition. Schweitzer admits that he is unable to explain the purpose of this exceptional arrangement. This investigator has made the most extensive practical study of the lymph system of the tissues about the dental apparatus. By using several coloring masses for injecting the different portions, he attempted to ascertain the regional drainage of the lymph from the gingiva and the teeth.

The following is a summary which Bartels[9] has given of the results obtained by Scwheitzer: The gingiva contains an extremely delicate, fine meshed network from which lymph vessels arise, which partly pass outward, and partly continue their course inward. The outer drainage paths collect in plexuses which surround the two halves of the jaw like a wreath along the upper and lower fold of the mucous membrane of the cheek, and form median anastomoses. From the plexuses numerous twigs pass from all parts of the alveolar processes along the vicinity of the anterior fascial vein to all submaxillary glands. In rare cases also the submental glands have been injected from the region of the four lower incisors (one case each of Schweitzer, Dorendorf and Polya and Navratil[10]). The inner drainage pathways originate as the outer ones. Those of the upper jaw differ in their course from those of the lower jaw. The former pass through the mucosa of the hard palate and from the lateral end of the alveolar processes over the soft palate and the pharyngeal wall downward and enter directly into the deep cervical glands. Generally they empty into the glands of the same side, but not rarely they cross and pass into the corresponding glands of the opposite side. The inner drainage pathways of the mandibular gingiva pass from the region of the incisors along the lingual surface of the jaw through

the mylohyoid muscle to the anterior submaxillary gland, and from all regions along the transitional fold to the deep cervical glands.

As to the pathways draining the teeth, Schweitzer admits that he has not reached complete and final issues; some conclusions are still represented as "probabilities." He says:

> As lymph paths from the teeth of the upper jaw, at least for part of them, we may consider as very probable, lymph vessels which emerge from the infra-orbital foramen or smaller secondary openings to the outer surface of the maxilla and pass to the submaxillary glands (media and posterior). In the lower jaw the lymph flows through rami dentales into lymph paths which course within the mandibular canal. Although it has hitherto not been possible to follow the latter vessels to their terminal passage into a lymph gland, we may assume, from analogy of the inner drainage of the gingiva, that they empty into the deep cervical glands or in part to the submaxillary glands.

As we shall show later, we can verify the correctness of this supposition; we have succeeded in injecting these lymph vessels in their entire passage from their exit at the infra-orbital and the mental foramen to their entrance into the submaxillary glands (Fig. 8).

The accompanying table is one set up by Schweitzer, which shows the drainage of the different regions of the gingiva, demonstrated chiefly by the results of injections with differently colored injection masses. Although he warns that separation of the glands according to regional sources be made only with some caution, because of the possibilities of the anastomoses, he assures that clinical experience is entirely in accord with his experimental evidences. Of particular interest are the extensive statistical observations of Partsch[11] and Ollendorf[12] about the swelling of lymph glands in morbid conditions.

This picture of the lymph system of the gingiva, the peridental membrane and the dental pulp will be more complete if it is seen in its relation to the blood supply. Wedl[13] was the first to demonstrate and accurately describe the location, general arrangement and course of the blood vessels in this region. Schweitzer has added some interesting features, especially about the vessels of the dental pulp. At the apex, between the dense fibers, we find a loose connective tissue which surrounds the larger vessels and nerves. Such loose interstitial connective tissue also fills the spaces between the bundles of fibers of the peridental membrane, in which course the numerous blood vessels which ascend from the depth of the alveoli toward the gingiva. These vessels communicate with the vessels of the pulp, with those of the medullary spaces of the alveolar wall and with the vessels of the gingiva. Near the surface of the tooth there are long capillary loops; these become narrower toward the apex of the tooth and the neck of the tooth. The arrangement of the capillaries in the peridental membrane is quite unique. Both Wedl and Schweitzer describe peculiar round tufts of loops which Wedl was the first to compare with the glomeruli of the kidney, a resemblance which Schweitzer emphasizes in his illustrations, in which an actual connective tissue capsule around these tufts can be distinctly seen. Besides these singular formations there are capillary loops "en palissade." The peculiarity of this vascular arrangement is explained as a conformation due to unusual functional demands on a tissue of such structural and physiologic significance as is the case of the peridental membrane.

REGIONAL DRAINAGE OF LYMPH VESSELS (OUTER LYMPH PATHS)

From the Region of:	Upper Jaw into Submaxillary Lymph Glands			Lower Jaw into Submaxillary Glands		
	Anterior	Median	Posterior	Anterior	Median	Posterior
Incisors and canines	Only exceptionally one vessel	About ⅚	Almost ⅙	About ⅔	About ⅓	Occasionally
Premolars	0	About ⅔	About ⅓	Rarely one vessel	Almost all	0
Molars	0	Almost ½	A little more than ½	Occasionally one vessel	Almost all	Occasionally one vessel

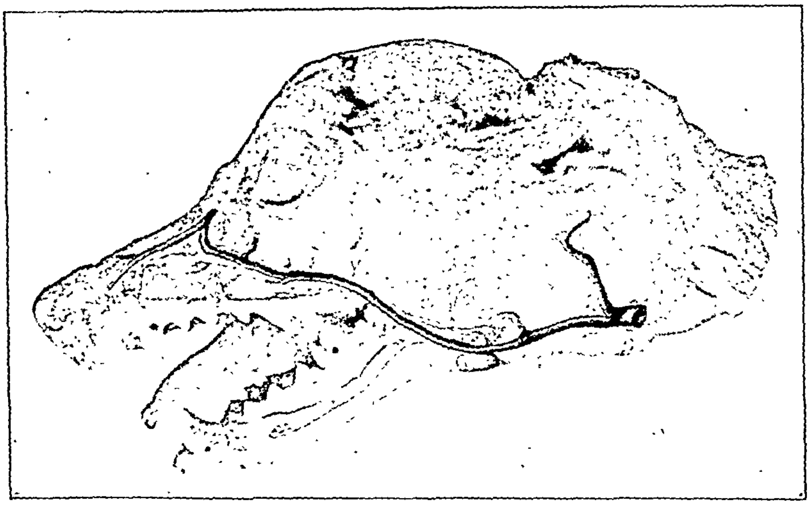

Fig. 9.—Drawing of dog's head showing injected lymph vessels from the infra-orbital and mental foramina to the submaxillary lymph nodes.

As to the dental pulp, Schweitzer insists that the number of vessels is greater than is usually given. The arteries entering the pulp divide into several parallel branches, which run toward the coronal extremity, giving off lateral branches mostly at right angles. These minute twigs form a precapillary network from which a very fine capillary network arises, located at the surface of the pulp between the odontoblasts. There are analogous venous networks; the veins leaving the pulp chamber are larger in number than the arteries. Being compressed at the apical foramen, the vessels in passing out spread out in rays, or fanlike. Even when still within the pulp cavity at the foramen where there is only cementum, divisions of the pulp vessels may branch off at obtuse or right angles, and pass through the cementum to gain the peridental membrane. De Saran[14] asserts that he has seen this very frequently.

In previously published work[15] we reported that we have indisputably demontrated that the lymph vessels of the dental pulp can be injected, not only in a retrograde direction by way of the gingiva, as Schweitzer did, but also by forcing the injection mass through the tooth directly into the exposed pulp tissue. The first investigation was limited to a study of the lymph supply of the pulp. The purpose of the present work was to follow the course of the outflowing vessels, to examine the extent of their communications with neighboring tissues, and to study their course in the mandibular and infra-orbital canals: in short, to fill out some gaps left in Schweitzer's results.

ABSTRACT OF DISCUSSION

Dr. Eugene S. Talbot, Chicago: Twelve years ago Dr. Latham and I did some work on dental pulp, but not in relation to the lymph channels. We were astonished at that time because of the large number of abscesses that form in the dental pulp. It is almost impossible to believe that abscesses form in the dental pulp without causing any pain, and later heal up, which naturally would show that there must be lymphatics connected with the dental pulp. It was not until Dr. Rosenow showed how the streptococcus travels through the blood stream into different parts of the body that it was fully explained how these germs pass through the ends of the roots into the dental pulp and form abscesses. We have on record one case, which was a wonderful illustration of the abscess theory. This pulp shows an abscess forming, another one healing and one practically ripe with the pus inside of it, showing the different changes that had taken place from the time of infection to the healing of the abscess in the dental pulp. If one makes a study of the dental pulp with a view to looking into this abscess formation, he will find a great many scars in the dental pulp where abscesses have formed and healed.

Dr. Edward H. Hatton, Chicago: These pathologic changes which are found about the gingivae and in the regions adjacent to these pus pockets can be explained in no other way than by the presence of lymphatics in the peridental membrane leading down along the teeth and into the pulp cavity.

Dr. Herbert A. Potts, Chicago: Aside from the histologic and anatomic interest of these studies, the demonstration explains many of our brilliant successes and many of our failures in the induction of local anesthesia. Two years ago Dr. Noyes told us the difficulty by which these injections were attended. I am sure that most of my success is due to the technic of the injection itself. Only by slow, steady injection do you obtain results.

Dr. Frederick B. Noyes, Chicago: I think you will find that this work has a bearing not only on local anesthesia but on the whole realm of dental pathology, especially the destructive inflammations which have their origin in the gingival spaces.

Reeducation of French War Cripples.—It was recently estimated that France had 300,000 disabled soldiers, with a monthly increase of between 6,000 and 7,000. They are cared for in national centers of physiotherapy, of which there is one for each of France's twenty military regions. To these centers are attached schools or workshops which the cripples may attend for purposes of reeducation. Independent of the centers, there are also civil schools for vocational reeducation, supported by both public and private funds; and finally there is the National Institute near Paris under the joint direction of the Ministries of War and of the Interior, with a well equipped military hospital, together with workshops and dormitories. Almost universally the "boarding-in" system prevails, that is, the soldier lives at the school and is under its direct discipline during his period of training.

FURTHER EXPERIMENTAL STUDY OF SURGICAL SHOCK *

F. C. MANN, M.D.
ROCHESTER, MINN.

A review of the results obtained in the extensive amount of work that has been done on the problem of shock, both experimentally and clinically, makes the point I have repeatedly emphasized particularly clear, namely, that the condition the surgeon calls shock may be due to a variety of causes.[1] The variation in the primary etiologic factor in a condition in which identical clinical symptoms occur is probably the cause of the more or less contradictory conclusions arrived at by investigators, both experimentally and clinically.

The value of experimental work on surgical shock is certainly decreased by the fact that it is impossible to reproduce the experimental environment, and the condition itself, in a manner identical to its clinical manifestation. From the results of a large series of experiments I am forced to conclude that the experimental investigator approaches, in only a few specific types, the condition that the surgeon studies clinically.

The future work on the subject termed shock will, in all probability, not concern itself with the condition as an entity, but with the different possible etiologic factors that could produce the clinical picture the surgeon has in mind. Two excellent examples of this form of research on the problem have recently been presented. They are the relation of fat emboli to conditions diagnosed as surgical shock, as shown by Bissell[2] and by Porter,[3] and wound shock of Cannon[4] and his coworkers. While in neither case have all the factors involved been explained, the positive fact that cases which the surgeon diagnoses as shock may be classified is of the greatest importance.

There is, I believe, one general statement that can be made to include all cases clinically diagnosed as shock, namely, that the fundamental cause of death in each instance is a failure of physiologic compensation. From the therapeutic standpoint one of the most important problems to solve in connection with shock is to determine why some persons fail to compensate for the various procedures to which they are submitted.

I have discussed in a previous paper[5] the effect of the anesthetic in relation to shock, but the anesthetic is of so much importance, both in experimental and in postoperative shock, that its effect should be emphasized. Recently, while performing some experiments, I found that a low blood pressure was produced invariably within an hour or two after the beginning of anesthesia, regardless of the experimental procedures employed. These results were proved to be due to impure ether. Careful experiments in anesthetic control should always be performed before it is concluded that an experimental procedure produces the symptoms of shock.

THE RELATION OF THE NERVOUS SYSTEM TO SHOCK

The relation of the nervous system, as a primary agent, to the condition which the surgeon diagnoses as shock is not clear. It is quite probable that the nervous system is a primary etiologic factor in some cases, particularly in those in which an anesthetic has not been employed. There are no experimental data extant in which such a relationship has been proved beyond a doubt. The results of numerous experiments that I have performed under light ether anesthesia have been, with the few exceptions previously recorded, uniformly negative. It certainly is possible to stimulate, either electrically or mechanically, one or all of the major nerves going to the limbs, for example, the sciatic and brachial plexus of a dog under constant surgical ether anesthesia, for as long as four hours, without producing the condition of shock. It should be emphasized that the marked fluctuation in respiration and blood pressure that occurs following such stimulation is not shock, and shock can be said to have occurred only when the cardinal signs of the condition are present at the end of the period of stimulation. In my experiments this has not occurred, but both respiration and blood pressure have quicky returned to approximately the normal condition. The same phenomenon follows section of the major nerves. Whether or not much reaction follows such a procedure depends mainly on the depth of the anesthesia. Under light anesthesia, section of the sciatic nerves and the brachial plexus produces marked changes in respiration and blood pressure; when deep anesthesia is employed, section of these nerves may produce only the slightest response in respiration or blood pressure. In either case shock does not follow section of the nerves. We have observed animals which, under light anesthesia, have had a normal blood pressure eight hours after section of the major nerves to each limb (Fig. 1). I am inclined to believe that, in most instances in which the primary factor is the nervous system, the cause will be found to be of the nature of inhibition, as held by Meltzer.[6]

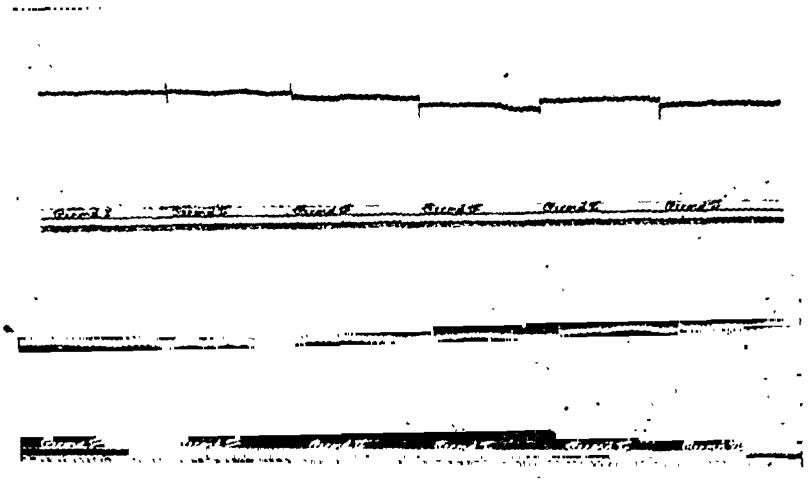

Fig. 1.—Kymograph record illustrating (1) an anesthetic control experiment and (2) the effect of section of the major nerves to each limb; Record I, normal blood pressure (140); Record II, immediately after exposing the sciatics and brachial plexuses; Record III, immediately after section of both sciatics and brachial plexuses. Each succeeding record was taken at intervals of an hour; thus, Record XII was taken nine hours after section of the nerves, and the blood pressure was 145.

Under only two conditions have I been able to produce death by nerve stimulation. One condition was produced by stimulating the nerve fibers that inhibited respiration when the animal was under deep anesthesia. Ether anesthesia seems to depress, and, when the tension is great enough, abolishes all respiratory reflexes except one before respiration ceases. The reflex that it does not abolish before the respiratory center fails is the one that inhibits respiration. Instead of ether depressing this reflex, it is quite common for its action to be increased. Under deep etherization it is possible, in many instances, actually to kill the animal by prolonged stimulation of nerve fibers that inhibit respiration. The stimulation of some nerves, as the central end of the vagus and the superior laryngeal, usually inhibits respiration for a short period. As the stimulation is continued, however, respiratory movements soon return, owing either to a decrease in the reflex or, what is more probable, to an increase in the chemical stimulation of the nerve center. It is rarely possible, under light surgical anesthesia, to inhibit respiration by the stimulation of these nerves for a long enough period to jeopardize the life of an animal. As the ether tension is increased, the length of time the respiratory movements are inhibited is prolonged. Finally, in a large number of cases, under deep etherization, respiration fails to return, and blood pressure quickly falls, death ensuing. In other cases, while respiration is always inhibited for a time, recovery occurs. In the earlier experiments the blood pressure was usually decreased, as much as one-half the normal pressure, before respiration could be inhibited long enough to produce death. However, it was found that by cautiously increasing the ether tension, many animals could be killed while the blood pressure was practically normal. The method of administering the anesthetic does not seem to be a factor in producing death. In most of our experiments the Connell[7] apparatus was used, in some instances a modification of McGrath's[8] method, while in still others only the cone method was used. While it is possible that death in these cases may be due to factors other than the inhibition of respiration and asphyxia, there is no evidence to show it. I have never been able to obtain this result by stimulating nerves that did not inhibit respiration. Death will not occur while insufflation or artificial respiration is maintained, if the ether tension is not above that compatible with life. Death under deep etherization has not been produced except in connection with inhibition of respiration. The process producing death in such experiments seems to be as follows:

For some unknown reason, ether does not abolish reflexes that inhibit respiration as long as the respiratory center responds. Under deep etherization the threshold of the cells of the respiratory center is greatly increased to the chemical stimuli. A point is thus reached at which the center will respond to the inhibitory reflex, and not to the increased carbon dioxid in the blood. At this time the stimulation of inhibitory fibers will produce death, and, owing to the deep etherization, quite quickly in many instances. Attempts have been made to produce the same result by both methods of stimulating the nerves other than by electricity or deep etherization. To date, however, all attempts have failed (Fig. 2).

[8] McGrath, B. F.: Anesthesia in Surgical Research, Surg., Gynec. and Obst., 1914, **18**, 376-377.

It has been thought for a long time that inhibition of the heart, due to stimulation of the vagus, might produce death in mammals, and it has also been suggested that a reflex producing inhibition of the heart might also end fatally. In a few instances in this series of experiments such a result seems to have been produced. However, to the present time, death, owing to apparent reflex inhibition of the heart, has not been produced by stimulation of any nerve except the superior laryngeal, although it would seem that the central end of one vagus with the other intact would be effective. As this reflex disappears under deep etherization, it appears that death could occur only by reflex inhibition of the heart under light anesthesia. Such was the case in these experiments (Fig. 3).

What practical bearing such experiments have on the shock problem cannot at present be stated. Death is produced so suddenly and so strikingly under these conditions that it seems highly probable the same thing has occurred in man. It is quite possible that deep etherization and inhibition of respiration during the time in which operations are being performed in the region of the neck, axilla and diaphragm (regions in which traumatic procedures are prone to produce stoppage of respiration) are responsible for some of the sudden deaths on the operating table that the surgeon has diagnosed as due to shock.

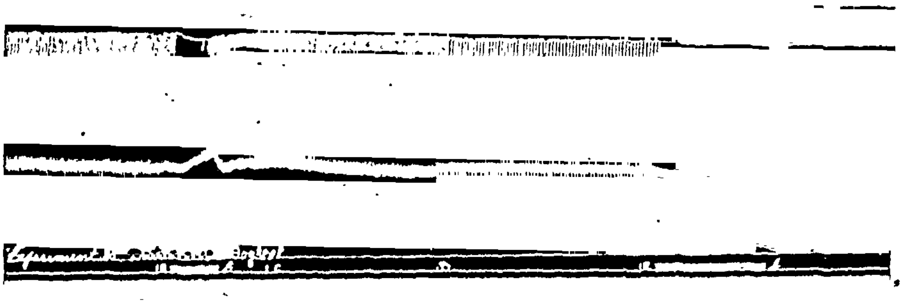

Fig. 2.—Kymograph record showing the effect of stimulating the central end of the vagus [illegible] anesthesia. Normal blood pressure was 115. At signal *a*, [illegible] and the control end of the left vagus was stimulated at *b* until respiratory movements returned. During the interval *D* (sixteen minutes) ether tension was increased. At *a* the ether was discontinued, and at *b* the vagus was again stimulated, and death occurred.

THE RELATION OF FLUID VOLUME TO SHOCK

The conception that in most of the cases which the surgeon diagnoses as shock the patients are in a pathologicophysiologic state, in which the cause of the symptoms is a loss of circulatory fluid, has been adversely criticized, because of the clinical distinction that is made between hemorrhage and shock. This has been due, I believe, to a failure to consider the fundamental likenesses and differences between the two conditions.[9] The symptoms of this form of shock and of hemorrhage are, in the main, due to the loss of circulatory fluid. In general, after hemorrhage, the vascular system is capable of functioning, and the mechanism controlling fluid volume is able to at least partially compensate for the loss. In the condition of shock, however, not only is there a loss of circulatory fluid, but the mechanism which controls fluid volume is also, and possibly primarily, greatly impaired. That is the reason why, in the former condition, intravenous injection of salt solution is of distinct value, while even the so-called colloidal solutions do not remain long in the circulation in the latter condition.

Janeway and Jackson[10] have shown that a circulatory failure, which presents the typical signs of shock, may be produced in dogs by a partial occlusion of the inferior vena cava at its point of entrance into the thorax. This has been corroborated by other investigators.[11] It seems that, for the most part, the result is due to the effect of the occlusion on the portal circulation and the liver, because it is well known that ligation of the inferior cava at a point just below the entrance of the hepatic veins is a perfectly safe surgical procedure in most dogs. The collateral venous return is such that a ligature thus applied does not produce any of the symptoms of shock. The ligation of the portal vein will always cause death in a few hours. Even partial occlusion of this vein, as sometimes occurs in a badly made Eck fistula, will produce death in a couple of days.

In a recent series of experiments, I have attempted to determine the relation of the volume of capillary and venous beds to the signs of shock. Only a brief preliminary report can be made of these experiments. The method consisted in including in a strong ligature all the structures to each limb except the major artery. In this manner the major artery was allowed to pump blood into the limb, from which all venous and lymph return was obstructed. The results of a sufficiently large series of experiments are in general agreement. The first effect of such a procedure is a slight and ordinarily transient rise in blood pressure. The blood pressure, as a rule, soon decreases and at the end of two hours it has only about half its initial value. At this time the animal generally exhibits the signs of shock. If the ligatures are then removed, recovery usually takes place. When the ligatures are left on for a long period of time, there may be an initial rise in pressure following their removal, but it subsequently decreases. When the ligatures have been applied for a very long period, the removal produces a further drop in blood pressure, and eventually, death. To a lesser degree these results may be obtained when only three limbs are used. From the results of such experiments it would seem that a condition producing stasis in a large capillary field would produce the signs of shock. It should be emphasized that simple vasomotor dilatation will not cause this condition. Section of the nerve supply to all the limbs does not produce the signs of shock (Fig. 1).

THE TREATMENT OF SHOCK

The treatment of shock may be divided into: (1) general measures, (2) the use of drugs, (3) attempts to restore the fluid volume, and (4) special measures. In studying any form of treatment of shock experimentally, it is necessary carefully to standardize the experimental procedures. In this series of investigations the routine method of experimentation was as follows:

---

[9] Mann, F. C.: Shock and Hemorrhage: An Experimental Study, Surg., Gynec. and Obst., 1915, **21**, 430-441.

[10] Janeway, H. H., and Jackson, H. C.: The Distribution of Blood in Shock, Proc. Soc. Exper. Biol. and Med., *1914-1915*, **12**, *193-197*.

[11] Erlanger, Joseph; Gessell, Robert, and Gasser, H. S.: An Experimental Study of Surgical Shock, The Journal A. M. A., Dec. 22, 1917, pp. *2089-2092*.

The animal (dog) was etherized in a closed cabinet, intubated, and a constant surgical anesthesia maintained by means of the Connell apparatus. The carotid blood pressure was recorded with a mercury manometer. Marked changes in the temperature were prevented by the judicious use of an electric pad. After a normal record had been obtained, the abdominal viscera were exposed and gently sponged, about every fifteen minutes, with dry gauze. When the blood pressure had decreased and remained rather stationary at the desired point, which occurred usually from about one to two hours after exposure of the viscera, the viscera were returned to the abdominal cavity and the wound was repaired. After waiting a sufficient length of time to determine definitely that the blood pressure did not increase, the procedure designated to improve the condition of the animal was instituted. The blood pressure was taken as a criterion of the condition of the animal because it is the easiest indication to record and compare. It should be emphasized that the anesthetic was constant throughout the experiment. This removes the possibility of the ether producing an error in either the interpretation of the blood pressure record or the general condition of the animal. Careful anesthetic control experiments were performed, the etherization being maintained at the same tension and for a length of time equal to the shock experiment. It should be noted that practical conclusions can be drawn only from the results obtained as applying to a condition in which the signs of shock were produced by exposure of the abdominal viscera. If the blood pressure is allowed to decrease until it is much less than half the normal pressure, it is rarely possible to restore it by any known method. This is an important point to consider in placing a value on any method of treatment.

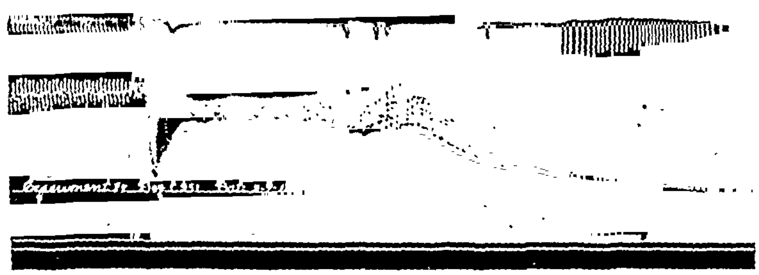

Fig. 3.—Kymograph record showing the effect of stimulating the superior laryngeal nerves under light anesthesia. At *a* ether was disconnected and signal *b* marks the period of stimulation of the superior laryngeal nerve, death occurring. This record is difficult to interpret, but it would appear that inhibition of the heart was the major factor producing death.

The general measures employed consisted of placing the animal in the head-down position, and the application of heat, etc. A slight amount of benefit has been obtained by such methods in experimental shock. In fact, it was found to be of distinct value to keep a heating pad under the animal throughout the experiment, care being taken to apply only a moderate amount of heat.

Drugs are employed for one or two purposes, either as a stimulant to the circulatory system, as strychnin and camphorated oil, or to produce vasomotor constriction, as epinephrin or pituitary extract. The results of the experiments corroborate our previous investigation on the use of stimulants in experimental shock. In none of the experiments was any benefit derived.

The value of the use of vasoconstrictors in the treatment of shock is still an open question. In the first place, although the decrease in blood pressure is of great importance in shock, it is not known whether or not its increase by means of vasomotor constriction is in itself of much permanent benefit to the organism. In the second place, none of the vasomotor constrictor drugs produce a very prolonged effect. In experimental shock it is not possible to maintain blood pressure for a very long period of time near to the normal value by the use of the vasoconstrictor drugs. In our experience pituitary extract produced a more prolonged action, and seemed to be of somewhat greater benefit than epinephrin.

A large number of artificial fluids have been devised with which to attempt to restore the volume of fluid in shock. Our series does not yet include experiments from which positive conclusions may be drawn in regard to all of these. However, they have furnished enough data to justify some tentative conclusions in regard to their use in experimental shock.

1. Physiologic sodium chlorid solution is the least valuable of all the artificial fluids, although hypertonic sodium chlorid solutions are of value.

2. The making of the artificial fluid alkaline definitely enhances its value.

3. The use of glucose in the injected solution is also of definite value.

4. None of the saline solutions alone will maintain blood pressure for more than a very short period of time, even when it has been lowered to but a slight degree by exposure of the abdominal viscera.

5. The employment of the so-called colloidal solutions, such as those containing acacia or gelatin, is of distinct value. The intravenous injection of these fluids will often restore and maintain the blood pressure for several hours after it has been decreased to at least one-half its normal value by the exposure of the abdominal viscera.

6. From these results it would seem that the ideal artificial fluid should contain (*a*) some substance to increase its colloidal properties, (*b*) an alkaline salt, and (*c*) glucose.

7. It should be noted that none of the artificial fluids will give as good results as whole blood or blood serum.

The value of transfusion in the treatment of shock is well known. In this series of experiments, citrated blood produced very good results. In order, however, approximately to restore blood pressure and maintain it, the amount transfused must be comparatively large. About 30 c.c. per kilogram produced the best experimental results. Such an injection will restore and maintain blood pressure under the experimental conditions outlined herein.

Blood serum seems never to have been used in the treatment of shock. In our experiments the intravenous injection of homologous serum has produced as good results, and, in most experiments, better results, than any of the methods employed in the treatment of experimental shock. In none of the experiments in which the blood pressure had not decreased below one half of its original volume did the injection of serum fail to restore and maintain it for several hours. The best results were obtained by relatively large doses, 20 c.c. per kilogram. The serum was prepared by bleeding healthy dogs into sterile bottles which were placed on ice until it was desired to use the serum. From 35 to 40 per cent. of serum can be obtained in the dog in this manner from whole blood.

When blood serum, 20 c.c. per kilogram, is injected into the animal in which blood pressure has been decreased one-half, as the result of exposure of the abdominal viscera, it produces the usual rise in blood pressure and an increase in the amplitude of the heart, which occurs whenever an intravenous injection is made. However, the increase in blood pressure is usually greater, although it may take place more slowly, than when any of the other injection fluids are used, with the exception of whole blood when used in amounts equal to the amount of blood from which the serum was obtained. The blood pressure seldom decreases subsequently, or only to a slight extent, and usually, with the passage of hours, it increases until it may be greater than at the beginning of the experiment. I have not been able to obtain equally good results by any other method, except by the use of large amounts of whole blood.

Whether or not the use of serum will ever prove of any practical value, I do not know. The employment of large amounts of serum other than homologous serum would probably be very dangerous. It is possible that the latter serum might be of value under conditions in which the serum could be kept and whole blood could not be obtained.

The special measures employed in shock, such as rebreathing, have never been shown to be of much value under experimental conditions.

SUMMARY

The term "shock" is used by the surgeon in describing a definite clinical condition; it is probably due to a number of causes. In general, however, all cases may be included in two groups. One group contains the cases in which the clinical manifestation follows some time after the occurrence of the conditions incident to the shock. The other group includes the cases in which a severe or fatal condition supervenes immediately on receipt of the active agent. Experimentally, either condition can be produced by few of the methods which may be compared to their clinical manifestations. Chief of the methods by means of which a condition simulating the cases included in the first group can be produced experimentally is exposure of the abdominal viscera. The symptoms thus produced are due to a loss of circulatory fluid, probably due to, or associated with, a failure of the mechanism to control fluid volume. The signs of shock may be produced by the loss of an amount of circulating fluid that can be sequestered into capillary beds of venous trunks of the four limbs. The part the nervous system plays in the cause of shock is undetermined. It cannot be proved beyond doubt, experimentally, that shock is an etiologic factor, although clinically it seems to be definitely established that it is responsible for death in some cases, and in such cases it will probably be found to be of the nature of inhibition. This group might include a large number of the cases contained in the second group. Experimentally, sudden death has been found to occur under deep etherization following stimulation of the nerves that inhibit respiration. It has also been produced under light etherization by the stimulation of nerves that produced an associated reflex inhibition of the heart. Either of these results may also occur clinically and the cause of death be described by the surgeon as shock. In the treatment of shock, experiments have not shown that the employment of drugs, either as stimulants or as vasoconstrictors, possesses very much value. The logical procedure, at least from the experimental standpoint, in the cases included in Group 1, would seem to be to attempt to replace the lost fluid. The best means of doing this is by the intravenous injection of large amounts of whole blood or blood serum. Some of the artificial solutions give good results. The ideal artificial fluid should contain, (*a*) some substance to increase colloidal properties, (*b*) alkaline salt, and (*c*) glucose.

RECONSTRUCTION OF THE COMMON BILE DUCT *

J. SHELTON HORSLEY, M.D.
RICHMOND, VA.

Defects in the common bile duct may result from errors in operative technic, from strictures following ulceration or trauma, or from neoplasms. Since excision of the gallbladder has become a frequent practice, possibilities for injuring the common bile duct, particularly in inexperienced hands, have multiplied.

In an effort to devise some method that would be satisfactory in reconstructing the common duct, various procedures have been devised. Sullivan[1] described an operation in which a rubber tube is sutured into the stump of the hepatic or the remaining upper end of the common duct, carried into the duodenum, and surrounded with neighboring tissue and omentum. Molineus, according to Walton, has suggested the use of the appendix for reconstruction of the common duct. However, it is often difficult to secure a satisfactory appendix, the nutrition of the transplanted appendix would be very problematic, and it would carry bacteria it normally contains, which may cause cholangeitis. It is for the last mentioned reason that it has been found unwise to connect the gallbladder with the colon instead of with the duodenum.

Lewis and Davis[2] have used experimentally transplanted fascia from the abdominal wall to repair defects in the common bile duct of dogs. Stropeni and Giacinto[3] reported experiments in which a portion of a vein was used to fill a defect in the common duct.

Walton[4] reviewed bile duct surgery and described an operation in which he uses a duodenal flap. Eliot[5] has given the recent literature on repair of the bile ducts, laying particular stress on the work of European authorities.

Moynihan[6] suggests the use of the jejunum in the same manner as the Y gastro-enterostomy of Roux. The upper part of the jejunum is cut across and the proximal (oral) end sutured end-to-side about 12 inches below the distal end. The distal end is then sutured to the gallbladder (Fig. 2). Clinically, if the gallbladder was normal, a cholecyst-enterostomy could be done, so the practical application of such an operation would be only where the end of the bowel must be attached to a small contracted gallbladder, or possibly to the stump of the hepatic duct. I have done six experiments after this method of Moynihan (Fig. 3). In all of them the dogs died.

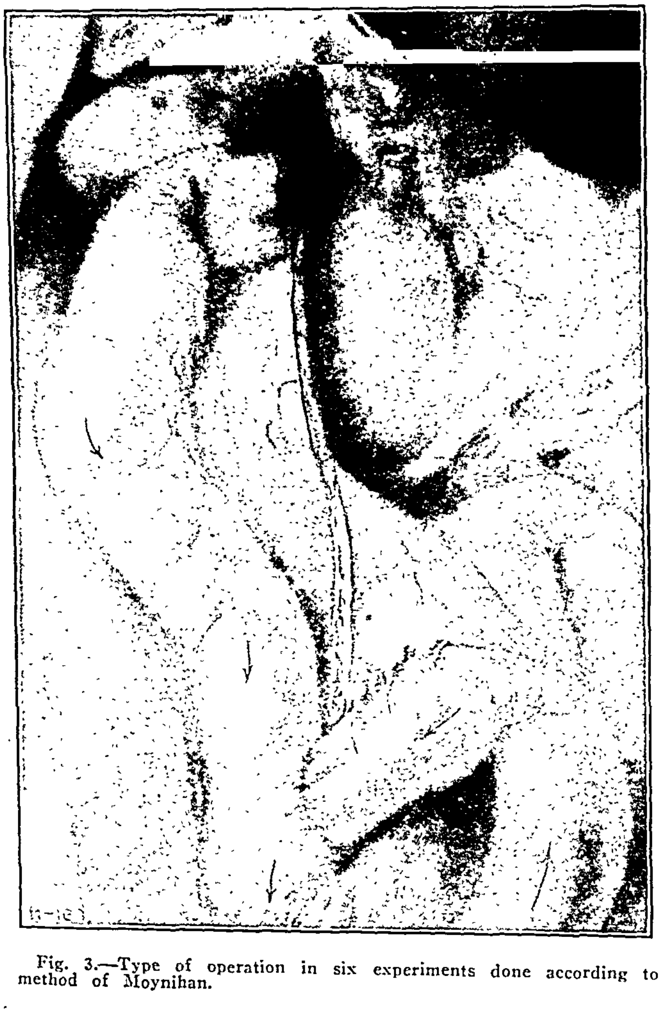

Fig. 3.—Type of operation in six experiments done according to method of Moynihan.

The thin gallbladder when sutured to the thick intestine of a dog readily tears, and the powerful peristalsis pulls loose the sutures. In man, of course, the same anatomic conditions do not exist; but with such fatal results experimentally I would be unwilling to try this operation clinically, even with more favorable tissue.

It occurred to me that probably the transplantation of an everted vein might be successful. Theoretically, the advantages are that the vein, when turned inside out, would have the endothelial coat outside, and this would become adherent to the endothelium of the peritoneum and the surrounding raw surface and the nutrition of the vein be thereby readily established. The vein offers a thin, well organized tube which should require a minimum amount of nutrition as compared with a thick tube of fascia, and if the epithelium from the duct and the duodenum would grow in from the ends of the transplanted vein, we might find a permanent tube of definitely organized tissue that would be satisfactory. These theoretical premises were not borne out by experimental work, as will be explained later.

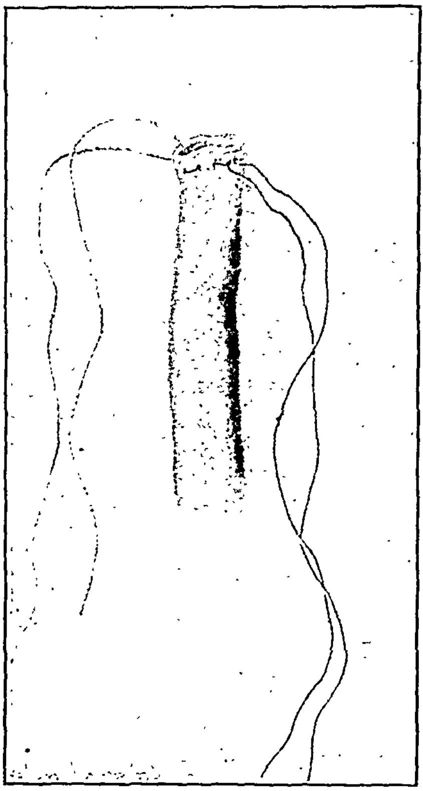

Fig. 4.—Segment of external jugular vein, which has been removed and turned inside out, with catgut and silk sutures placed in position.

TECHNIC

Sixteen experiments were done on dogs in which the following technic was developed:

The vein used is from the external jugular, which seems to serve best for this purpose in a dog and is very large. A ligature is placed at the lower portion of the external jugular, and after the vein has been dissected clean of fat another ligature is placed at the upper end. The length of the segment removed should be at least double the length of the duct to be reconstructed, as the vein contracts greatly. After removal a mosquito hemostat is inserted in the segment of vein at one end, and grasps a bite at the other end; then by pulling on the forceps the vein is turned inside out. The vein should be kept moist with salt solution, in order that it may be handled more satisfactorily. A suture of small tanned catgut is inserted at one end after the manner of a purse-string suture. It is tied so as not to constrict the caliber of the vein. This suture acts as a collar. Opposite the knot in the catgut a silk ligature is placed and left untied (Fig. 4). The vein is now ready for transplanting.

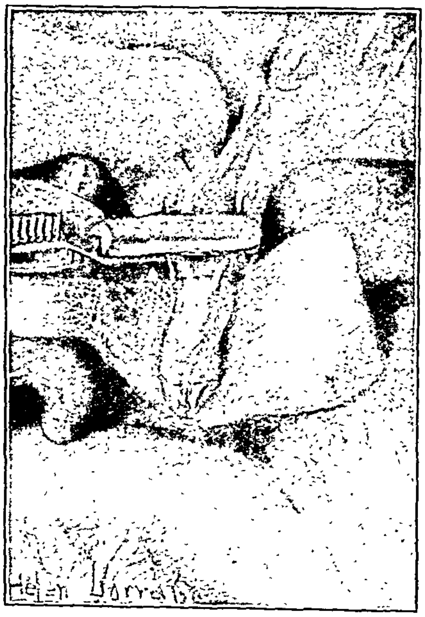

Fig. 5.—Common duct has been dissected free and serrefine placed on upper extremity. Dotted lines indicate point at which it is to be resected.

The common bile duct is dissected free, and a serrefine whose spring has been weakened as for blood vessel work is

placed on the upper part of the duct (Fig. 5). It is important to preserve the peritoneal covering of the duct as much as possible, for this facilitates the healing of the transplanted vein to the stump of the common duct. A ligature is placed on the duct close to the duodenum, and the portion between the ligature and the serrefine is excised. A needle threaded with rather stout silk doubled transfixes the stump of the common duct (Fig. 6). This is a tractor suture and is made long enough for the four strands to traverse the segment of vein, take a small tube, as shown in Figure 11 *a*, and then dangle free in the bowel.

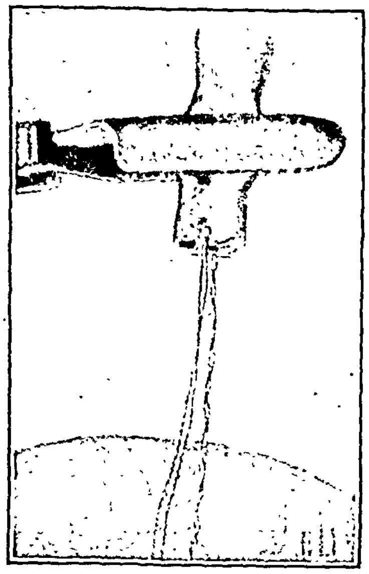

Fig. 6.—Duct has been resected and upper stump transfixed with double silk used for a tractor suture.

This tractor suture is not tied on the common duct for fear of occluding it, but is merely inserted. The object of this suture is twofold: First, it will afford immediate drainage for the bile along the suture, and, second, the thread with its attached rubber tube in the intestine will tug at the end of the duct and prevent its retraction from the vein. If the suture is anointed with petrolatum it is more easily handled.

Mosquito forceps are introduced through the segment of vein and catch the four strands of the tractor suture, drawing them through. Then two of the strands are threaded in a large needle, passed through a short piece of small rubber tube, and tied firmly to the other two strands (Fig. 7). One end of the catgut of the purse-string suture on the vein is now threaded in a small curved needle and catches a small bite in the duct about one-third inch from its end. It is tied snugly while pulling up the vein and pulling down the tractor suture so that the stump of the duct is invaginated into the vein. The ends of the catgut are cut short. Then the end of the silk ligature that was previously inserted into the vein is threaded into a needle, catches a bite of the duct, and is tied at a point about opposite the place where the catgut suture was tied. The silk is left long in order to bring the omentum up later on. In this manner the vein is fixed to the stump of the common duct which has been invaginated into the vein.

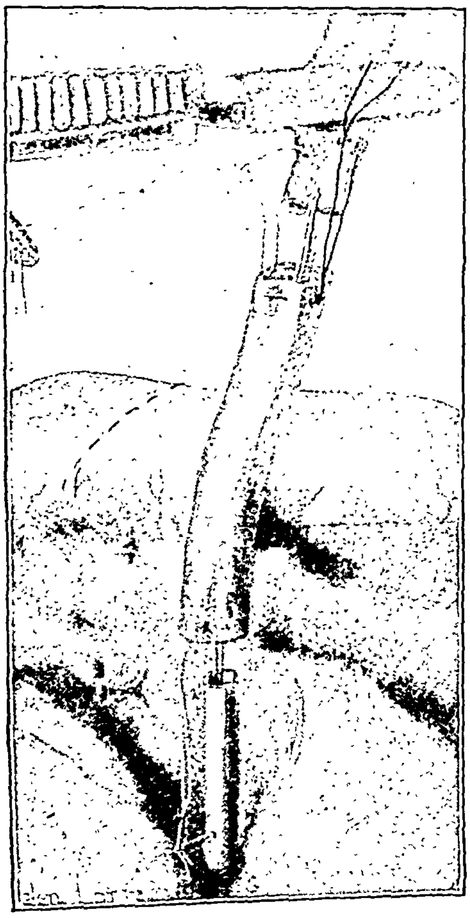

Fig. 7.—Tractor suture has been caught by mosquito forceps which were introduced through segment of vein, pulled through vein, carried through small rubber tube, and tied. Catgut and silk sutures have been carried through stump of common duct and are about to be tied.

A transverse or oblique incision is now made on the duodenum, going down to the mucous membrane but not through it. At the point of incision farthest from the common duct, the mucous membrane is punctured (Fig. 8). A silk or linen suture is passed through the edge of this puncture and catches the vein in at least two places. This suture is inserted from without in and returns from within out, so making a mattress stitch. It is tied, and the tractor suture on the common duct, together with the piece of rubber tube, is pushed through the hole in the mucous membrane (Fig. 9). A few interrupted mattress sutures bury the transplanted

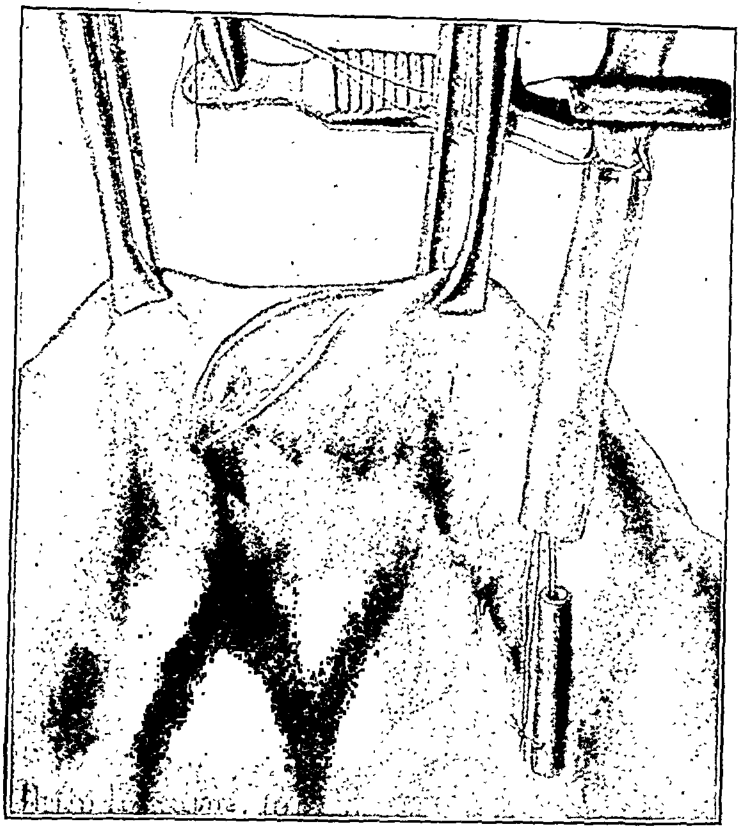

Fig. 8.—Incision is made in duodenum down to mucosa. Mucosa punctured at end of incision farthest from duct, utilizing the principle of Coffey.

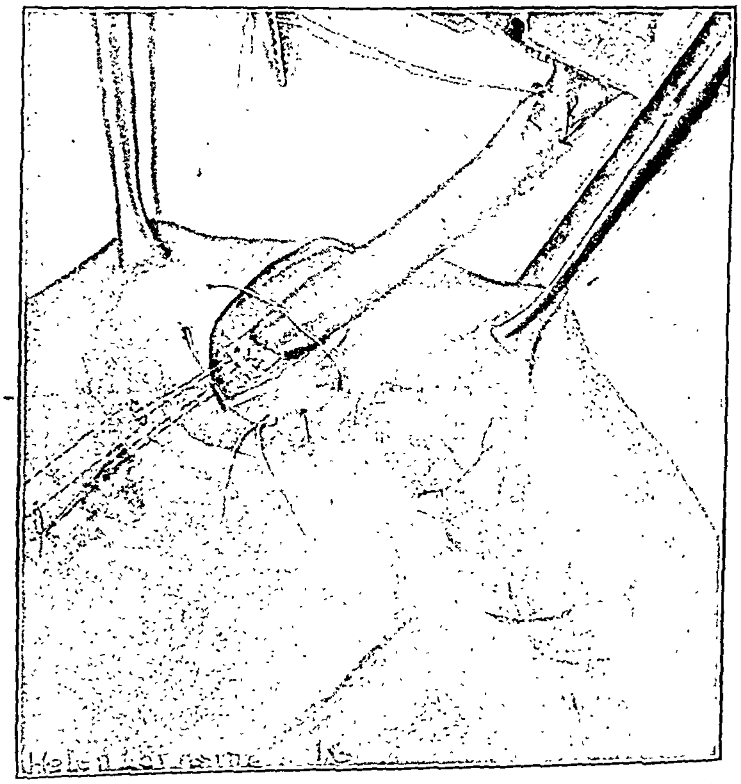

Fig. 9.—The tractor suture with rubber tube has been placed within the bowel. The vein has been fastened by a mattress suture through mucosa, and the wound in the duodenum is being closed.

vein, making its insertion oblique and using the mucous membrane as a valve as recommended by Coffey. The end of the silk suture that holds the vein in position at the upper stump of the common duct is now threaded on a needle, and a piece of omentum is brought up and held around the transplanted vein by means of this suture (Fig. 10).

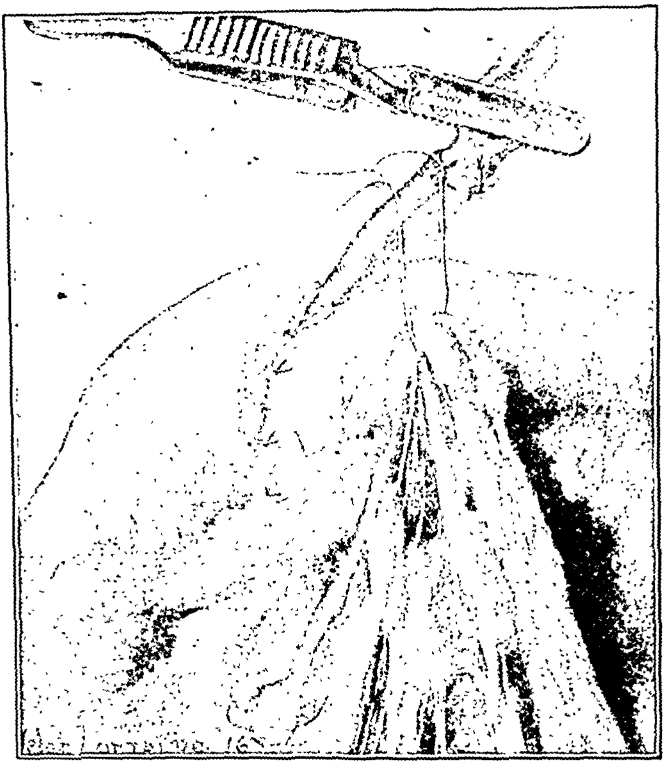

Fig. 10.—The long end of the silk suture in the upper part of the vein catches the omentum and holds it around the reconstructed duct.

RESULTS OF EXPERIMENTS

Of the sixteen experiments, in the first and the third dog there was no provision made for drainage of bile through the transplanted vein. Both died with leakage at the junction of the duct and the vein; the vein having become a solid cord. Six other dogs either died or were apparently about to die when killed within from seven to forty days after operation. In each instance there was occlusion of the transplanted vein.

In those that died soon there was usually leakage at the junction of the vein and the duct. One dog (Dog 14) died two days after operation, the abdominal wound having opened. Six dogs were in fairly good condition when killed from nineteen to forty-five days after operation. In one (Dog 7) the transplanted vein was distinctly patent thirty-six days after operation, and in another (Dog 13) nineteen days. In the other four the vein seemed to be well nourished, though it was occluded at the distal end. One dog (Dog 16) was killed under an anesthetic three and one-half months after operation. It had been well up to three weeks before being killed. It then began to look bad and became emaciated and jaundiced. Postmortem showed the reconstructed duct occluded and much shortened, and the common and hepatic ducts enormously dilated.

Dilatation of the common and hepatic ducts occurred in all cases, even when the reconstructed duct was still patent. This was probably due partly to interference with peristalsis and partly to pressure within the duct as well as to beginning obstruction.

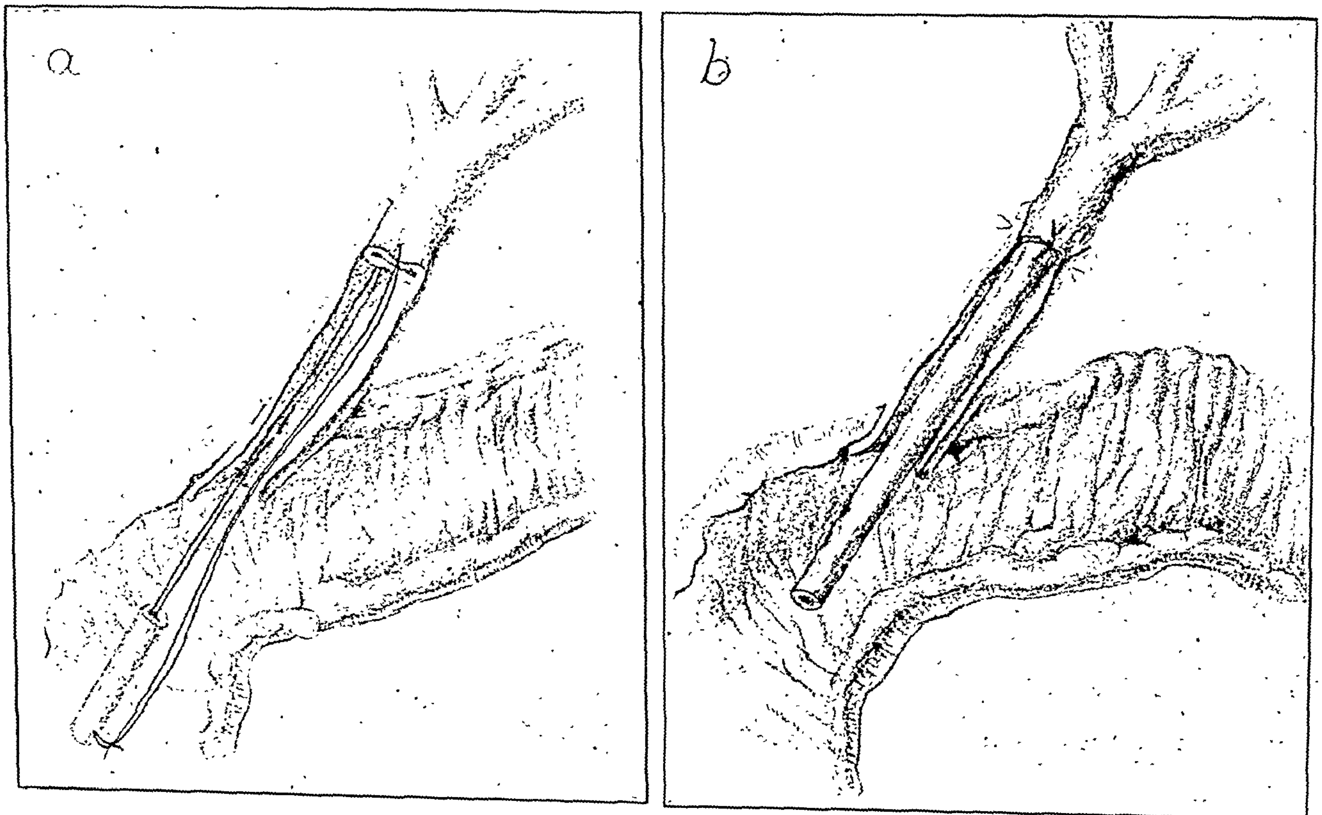

Fig. 11 A

Fig. 11 B

Fig. 11.—Sections showing: a, relation of the tractor suture in the reconstructed duct; b, modification in which small rubber tube was used instead of tractor suture. It did not have any material advantage.

The practical conclusion from these experiments seems to be that while it is possible to reconstruct the common bile duct with an everted segment of vein, the final result is unsatisfactory. In man the immediate danger from the operation, leakage at the point of junction, could be largely avoided by drainage, which is impracticable in a dog. When a dog recovered from the immediate effect of the operation, it did well for several weeks; but if the animal was permitted to live long enough, it became ill from one to three months after the operation.

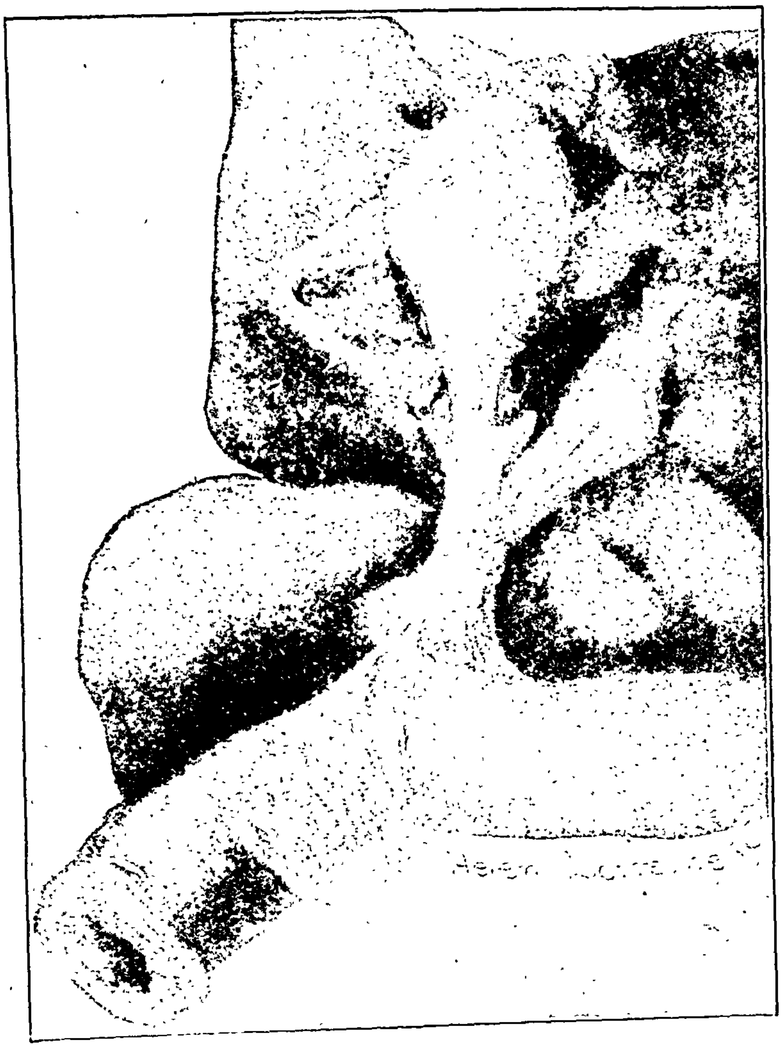

Fig. 15 (Dog 16).—Specimen removed 109 days after operation. The transplanted duct is greatly shortened, completely occluded and buried in a mass of adhesions. It shows as a short cord connecting the dilated ducts to the duodenum. The dog was in good condition until about two weeks before death.

The explanation of this failure is that it is due to contraction of the reconstructed duct, and analysis of the postmortem examinations and the microscopic findings throws some light on its cause. Though the everted jugular vein made a tube several times the caliber of the normal bile duct, contraction invariably took place. In some instances contraction was more rapid than in others, but it always occurred and, if the dogs were permitted to live, eventually there was occlusion.

Microscopic sections of the transplanted vein show a marked inflammatory round cell infiltration of the adventitia, the internal layer of the everted vein, whereas the outer layer, or the intima, with its adjacent coat, had very little infiltration (Figs. 17, 18, 19 and 20). This testifies to the irritating effect of bile on that layer of transplanted tissue with which it came in contact. Such continued irritation, resulting in prolonged infiltration with inflammatory products and small round cells, causes contraction.

COMMENT

There seems to be what might be called a biologic law of the immunity of tissue near an irritating discharge to the effects of that discharge. This immunity may be relative or absolute, but it appears to exist to some extent in the tissue immediately around the lining of the bile tracts, the bowel and the urinary apparatus. Operations, for instance, around the anus and in the perineum where contamination with fecal discharge cannot be entirely avoided are not often infected. In perineal prostatectomy, in which the wound is in close proximity to the anus, there is rarely infection, which is more common after the suprapubic operation, when only urine and no fecal matter come in contact with the wound.

The immunity of neighboring tissue to local irritating discharges is well illustrated by the healing of intestinal wounds. In a sutured intestine the peritoneal surface first unites, and soon after this the epithelium grows over the internal surface of the wound. Later, the submucosa and the muscular coats are repaired. The intestine finally straightens out, as shown by the early studies of Halsted and Mall, and repair eventually becomes practically perfect. Healing goes on with the fecal current flowing over the wound. But if a cut were made through the corium and all the layers of the skin of the arm, for instance, and the wound kept constantly bathed in fecal matter, as an intestinal wound is, repair, if it ever occurred, would be slow and with a large scar.

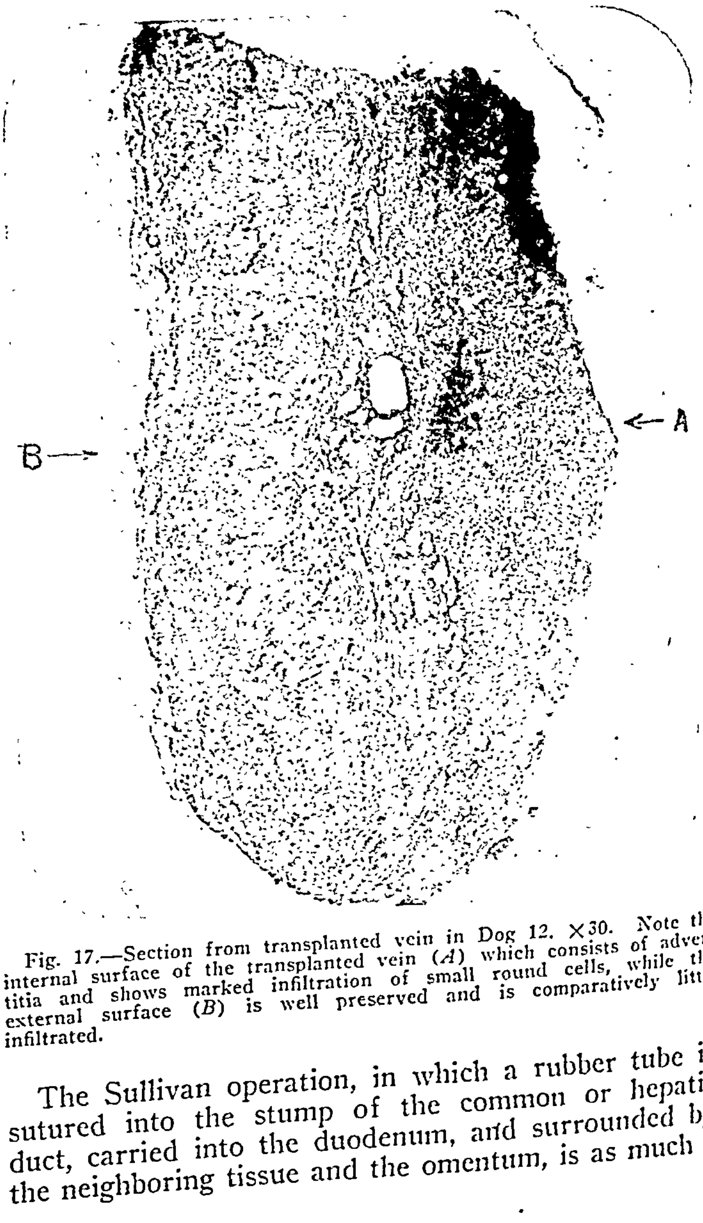

Fig. 17.—Section from transplanted vein in Dog 12. ×30. Note the internal surface of the transplanted vein (*A*) which consists of adventitia and shows marked infiltration of small round cells, while the external surface (*B*) is well preserved and is comparatively little infiltrated.

The Sullivan operation, in which a rubber tube is sutured into the stump of the common or hepatic duct, carried into the duodenum, and surrounded by the neighboring tissue and the omentum, is as much a transplantation of tissue as when fascia or venous segments are transplanted. In one instance tissues in the neighborhood are made to form a channel around the rubber tube, and in the other there is a free transplantation. The Sullivan operation results in a biliary fistulous tract, probably similar in general construction to an external biliary fistula that follows removal of a drainage tube after an operation that opens the bile tract. It is well known that the irritating effects of the bile and the resulting scar tissue tend to produce contraction and occlusion of such a biliary fistula to the skin. It has been asserted that in an operation of the type of the Sullivan operation, the epithelium from the stump of the duct would grow over the tract made by the tube and so prevent contraction. A similar hope was entertained by me in my early experiments, that the well organized and well nourished walls of a thin vein would form a satisfactory foundation for the epithelium to grow on. However, we found that unless the tissue has some immunity to the effects of an irritating discharge with which it is constantly bathed for a long time, inflammatory infiltration and contraction take place. In this respect the Sullivan operation, which utilizes the neighboring tissues, may be less liable to be followed by contraction than when tissue is transplanted from a distance, though the immunity of tissue outside the duct itself, even in close proximity to the duct, would probably not be very great.

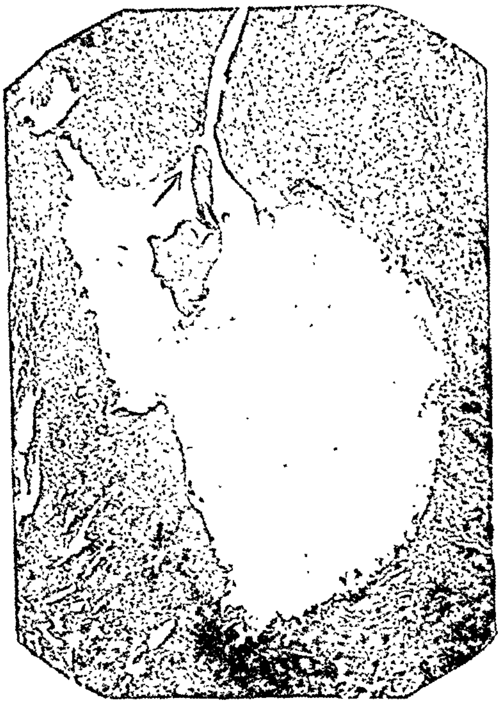

Fig. 20 (Dog 7).—Transverse section of transplanted vein, thirty-six days after operation. Note contraction, folding in, and round cell infiltration around lumen; × 30.

An interesting fact emphasized by these experiments is that constriction and occlusion of the duct do not result from contraction of the epithelial tissue but of the connective tissue. This is universally true. The striking deformities that are seen in the face after a burn are, as a rule, healed over with epithelium; but the contraction is due to the scar tissue under the epithelium which replaced the corium. So in stricture of the urethra, the surface is rarely raw, but is usually covered with epithelium, the stricture occurring from contraction of the connective tissue which has replaced the submucosa. It is, then, contraction in tissue that corresponds to the corium in skin or the submucosa of mucous membrane that is responsible for such deformities or for stricture, even though the surface is completely covered with epithelium. That epithelium does grow over at least a portion of the reconstructed duct is shown by one of the accompanying photomicrographs (Fig. 21); but this in no way prevents ultimate contraction of the tissue that replaces the submucosa. I call attention to this fact because in a number of instances in the literature, the assumption seems to be that if the reconstructed duct is lined with epithelium, no contraction will occur.

If epithelium is removed from the skin or mucous membrane, and if the defect is not too large and the corium or submucosa has not been materially injured by trauma or infection, repair will be perfect; but if the corium or submucosa has sustained any but the slightest injury, a permanent scar will result. Scars resulting from mechanical trauma, such as a cut with a knife, are notoriously less extensive than those that result from burns, infection or chemical injury. After mechanical trauma when there is no infection, the damaged tissue is destroyed or removed and the adjoining cells are not affected. But in an injury from a burn or from a chemical irritant, which for this purpose includes infection and irritating discharges, besides those cells that are entirely destroyed many adjacent ones are affected though they may not be killed outright. Later, they atrophy and are replaced by scar tissue. This necessitates repair not only of the tissue that is killed outright, but of the cells whose vitality has been impaired in a zone outside of that in which complete death of cells occurred, and calls for a high degree of hyperemia and extensive connective tissue formation, which means a prominent scar and marked contraction. In a reconstructed bile

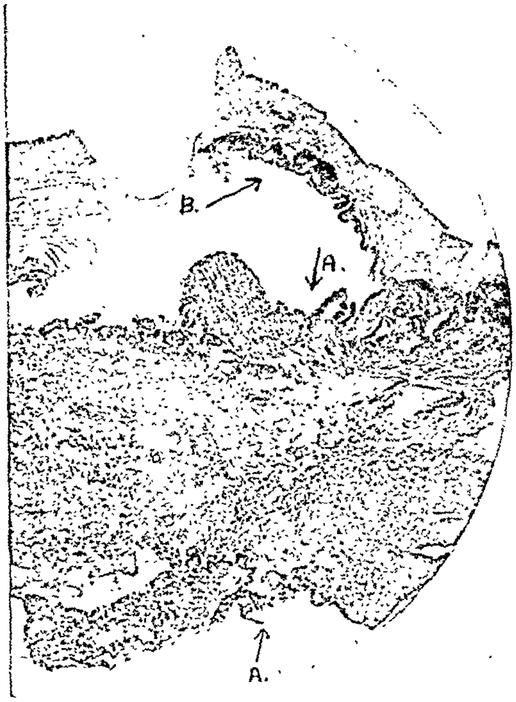

Fig. 21 (Dog 12).—Section of junction of transplanted vein with stump of common duct (*A*, *A*) twenty-three days after operation, × 30. Note that the columnar epithelium has grown a considerable distance over on the transplanted vein; but its attachment was slight and was partly broken loose during section (*B*).

duct where a vein or other tissue that has no natural immunity against the chemical irritation of bile is used, we have the very conditions that produce a large amount of scar tissue, so subsequent contraction inevitably ensues.

The conclusion may be stated that repair of any structure over which irritating discharges flow should be made by tissues that are either wholly or partly immune to these discharges. Repair of defects of the common duct, then, should be done with *a view to the* avoidance of subsequent contraction which will surely occur, whether epithelium lines the newly constructed tube or not, if nonimmune tissues foreign to this region are used. *It seems* that the most satisfactory reconstruction occurs when the stump of the common or hepatic duct is sutured to the mobilized mucosa and submucosa of the duodenum. In this way epithelial and subepithelial layers of tissue that are accustomed to the biliary discharges are employed; and if an accurate approximation is made, the submucosa of the duodenum unites with the corresponding tissue of the stump of the duct, and no more contraction should occur than would take place after suturing a wound in the intestine. Dr. William J. Mayo has employed such a technic in his clinic for a number of years, and similar work has recently been reported by Dr. Le Grand Guerry.

RECONSTRUCTION OF THE CHOLEDOCHUS

LE GRAND GUERRY, M.D.

COLUMBIA, S. C.

Surgeons are occasionally forced to the necessity of reconstructing the common duct. Surgical literature is full of case reports, and many methods have been advocated by equally as many writers, involving the transplanting of fascia, the transplanting of blood vessels, the transplanting of the peritoneal layer of the duodenum, and so on to the end of the chapter. Some of the operations are good and others are distinctly bad.

Experimentally many plans have been tried on dogs with varying degrees of success. Unfortunately, what will work in the dog laboratory will not always work in the human abdomen, and the simple method I present, although done independently under the force of circumstances seven years ago at our hospital, is not an original plan, for in reviewing the literature I find case reports of almost the identical procedure. I do not wish the foregoing statement to be construed as a criticism of the invaluable experimental work carried on by Crile, Cushing, Horsley and many others, for we owe a large part of our progress in surgery to such work. I feel, however, that when due allowance has been made, there is a tendency among some to test the final value of a given method in the experimental laboratory rather than under actual conditions in the human body.

In January, 1916, Mayo[1] published a splendid article on "Restoration of the Bile Passages," which every one interested in this subject should read. The method described in this article is almost identical in principle with the one under discussion. It appears to me that in our effort to find something new under the sun we have focused our thought too much on the experimental laboratory and have overlooked the most natural way of overcoming these defects in the bile passages.

REASONS FOR RECONSTRUCTION

Some of the reasons why it is necessary to reconstruct the common duct are as follows:

1. In case of permanent obstruction at the head of the pancreas, if the gallbladder is intact, we shall have plain sailing. Cholecystoduodenostomy is, however, a short-circuiting operation rather than a reconstructing of the bile passages. If the gallbladder has been removed, there will be another story to tell.

2. It may be necessary to restore the bile passages on account of inflammatory stricture of the common duct. If the stricture of the common duct extends above the junction of the cystic and hepatic ducts, it may be necessary to excise the strictures and then, if possible, apply the method to be described, or the stricture may be divulsed.

3. The common duct may be divided in the operation of cholecystectomy. As a matter of fact, injuries to the choledochus are usually the result of operative measures. If the accident is discovered immediately, repair is much easier than if a secondary operation is necessary to correct the injury. It is vitally necessary to remember here that the junction of the hepatic and cystic ducts which form the common duct is not always at a fixed point.

Whenever we attempt the operation of cholecystectomy, the point just mentioned must be constantly borne in mind. The usual position at which the cystic duct enters the hepatic duct is about three quarters of an inch below that portion of the hepatic duct which lies within the liver itself. However, the junction of these two ducts which form the common duct may occur as high up as the fissure of the liver, or they may run parallel with each other and unite almost at the entrance into the duodenum. According to Gray's Anatomy, they may remain independent throughout their course, or the junction may occur at any point between the fissure of the liver and the duodenum.

Not only, then, do we have the junction of the hepatic duct and the cystic duct at a point whose location varies, but the two ducts running a parallel course and in intimate association one with the other and at times overlapping each other. When this unusual anatomic situation occurs, unless the two ducts are isolated and identified before the gallbladder is removed, accidental injury to the hepatic or common duct can and often does occur.

A case within the last few months beautifully illustrates this point. A male patient, aged almost 60, had a large stone in the ampulla of Vater, producing obstruction of the common duct. The hepatic and cystic ducts were both distended to the size of one's index finger and could be clearly traced almost to the duodenum before the junction was effected.

RESULTS OF OPERATION

The three essential things to be accomplished by the operation are as follows:

1. In certain of the cases in which the duodenum is closely bound down by adhesions, its mobilization is most important, as we are thereby enabled to effect the anastomosis with greater accuracy.

2. This step I believe to be fundamentally necessary. The essential thing, as the illustration will show,

---

[1] Mayo, W. J.: Surg. Gynec. and Obst., 1916, 22, 1-6.

is so to mobilize the mucosa of the duodenum that when the suture line is completed, the mucosa and the submucosa of the duodenum will be directly united to the light structures of the hepatic duct. If this is done, we shall have a continuous epithelial lined passage, and contraction in all probability will not occur. This point illustrates the inherent weakness in many of the so-called autoplastic reconstructions of the bile passages. Some of the methods break down just here, in that they fail to provide a continuous mucus lined passage for the bile.

3. The third objective to be attained is the one so clearly set forth by Dr. Horsley in the preceding paper. His experimental work shows clearly that contraction may occur in an epithelial lined sinus: "Construction is due to contraction of underlying fibrous or connective tissue and not to contraction of the epithelium itself" (Horsley).

The absence of a proper submucosa as a covering for the line of union may bear the same relation to the contraction of the anastomosis as the corium does to a burn of the skin. We do not have contraction in a superficial burn of the skin, because the corium, which consists of connective tissue, that is, elastic fibers, contributes elasticity to the skin. This portion, also the seat of the sensitive layer, is not destroyed. On the other hand, however, contraction always occurs when the corium is destroyed. The point is that the corium bears the same relation to contraction following a burn of the skin as the submucosa bears to contraction following anastomosis between the common duct and the duodenum.

CONCLUSION

I wish to make this point perfectly clear. I am not setting up the claim that this is the *only* way of remedying these defects in the bile passages. We may be quite sure that in many instances this method will not be suitable. What I do contend, however, is that the plan has a sound surgical and physiologic basis.

As the illustrations will show, the method provides a continuous mucus-lined passage and a submucosa from a location and under conditions as normal as we may hope to obtain. It appears to me, then, that in the group of cases suitable for this method of relief, the bile passages may be restored as nearly as possible to a normal condition.

Briefly then, my experience with reconstruction of the bile passages is confined to seven cases. One particularly interesting point about the third case was that the stump of the hepatic duct was so short that, try as I might, it was quite impossible to suture the duodenum to the hepatic duct. Consequently the gap between the two, which was about one-half inch in length, was bridged by a small rubber tube about the size of a No. 9 catheter. To my intense delight, the tube was passed about the fourteenth day, and, after a slight external drain of bile which lasted for about one month, this patient has remained well ever since.

There were two deaths in the seven cases. One death in a woman aged 70 was due to surgical shock and followed the operation within three or four hours. The second fatal case was due to postoperative pneumonia. One patient, who survived the operation and was alive four years afterward, had a small external biliary fistula that drained bile intermittently. Her health, however, was much improved, and since then she has passed from under my observation. The remaining four patients have remained well ever since the operation, and may fairly be regarded as complete symptomatic cures.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. HORSLEY AND GUERRY

Dr. Arthur G. Sullivan, Madison, Wis.: I wonder if you fully grasp the significance of Dr. Horsley's statements as regards the influence of a lining epithelium on duct contracture? The question is constantly raised as to whether the epithelium actually grows and eventually unites in the new-formed canal made by my method. A sinus lined by epithelium is by no means insured against contraction. The old belief that epithelium itself would prevent contracture is not correct. Epithelium itself does not necessarily have any influence as regards keeping a duct patent, nor does its absence interfere with the discharge from a persistent biliary fistula. Do you ever worry that a persistent biliary fistula will close? Your chief worry is that it will not close. As long as there is obstruction so that the course of least resistance is for the bile to come outside, the bile will come outside, epithelium or no epithelium. You all have had experience with fecal and urinary fistulas and have worried considerably for fear they would stay open, although you knew full well that they were not lined by epithelium. As Dr. Horsley indicates, the character of the wall itself holds the secret as to whether a new-formed sinus will eventually contract, granting, of course, that there is a constant and regular discharge of bile through the sinus. The epithelium fully lined the new-formed ducts in my experimental work.

The various methods which have been proposed for bile duct repair have looked very well in the illustrations, but many of them cannot be utilized at all in the average case which requires duct reconstruction. The method portrayed by Dr. Guerry looks good, and it evidently has been successful; but to be candid, I can scarcely see that the end result of Dr. Guerry's operation, as indicated by his illustration, is at all different from Dr. W. J. Mayo's, in which he mobilizes the duodenum and sutures to it the divided hepaticus. I do not want you to get the wrong impression of my faith in the rubber-tube method. If you are faced with a predicament in which there is no gallbladder and no opportunity to unite the hepatic duct directly to the duodenum, put in a rubber tube and cover it with the tissues near at hand. As Dr. Coffey has stated, those tissues probably lend themselves better to the rather irritating effect of the bile than do those of a transplant. If you will do this, your efforts may be successful.

Dr. C. N. Davis, Chicago: Dr. Horsley made mention of some experiments done by me some three years ago. We worked with fifty dogs and transplanted fascial flaps in an effort to repair the common duct. Our results were good and bad. In confirmation of what Dr. Sullivan has said, we found that the ducts made by fascial flaps were lined by epithelium. The great majority of our animals were lost because of stricture, not through the fascial tissue, but at a point where the duct had been cut across. We tried to obviate this stricture by cutting the duct in an oblique manner. But this seemed to have no effect whatever. A few of the animals survived, but the great majority died because of the constriction where the duct was cut. Two or three years ago a Chicago surgeon resected the common duct in doing a gallbladder operation. A drainage tube was put in and the patient allowed to drain. Some three or four months after that we put a tube in and reconstructed the common duct over a T-tube. The bile discharged through the long end of the T-tube and discharged normally into the intestinal tract. The tube was left in place for six months and the patient gained weight. Everything went lovely. A few months later the tube was removed, and in a short time the patient's condition was as bad as before the operation. She was operated on again, and later the tube was taken out, with a like bad result. She was operated on a fourth time. A T-tube was put in, and the patient says it will be removed only from her dead body.

Dr. L. L. McArthur, Chicago: I had not the advantage of the recent experimental research work on bile tract restoration when I met with my first case in 1907. Dr. Sullivan's article had not then been published, so I improvised a means of reconstructing a common duct which had been injured in the preceding operation. The patient, who suffered two or three years with icterus whenever his fistula closed, but was relieved when it was open, desired something to be done. It was possible to find a dilated proximal common duct. The gallbladder had been removed at a former operation. Into this dilated common duct it was possible to introduce a rubber tube. There was no possibility in the cicatricial tissue which surrounded this field (he had had three previous operations) of finding the distal portion of it. So a pursestring suture was made in the duodenum at the point most closely lying to the proximal end of the common duct, and a tube introduced through an incision in the center of this area after a pursestring suture had been made in the common duct proximal end and a tube inserted. Reasoning that it was essential that that tube should come away not at once, but after some time, I did this: I turned back a cuff on the rubber tube about one-quarter of an inch, then turned that back again so that I had a round knob on the end of the tube about twice the size of the tube, narrowing its lumen, but permitting the bile to flow. With the proximal end in the common duct, it was easy to constrict the common duct, leaving its mucosa attached so that it brought it close to the duodenum. I wanted the tube to come away, but not too soon. I made it 8 inches long and let the 8 inches go down the duodenum, so that the constant peristaltic pulling for five or six weeks all that time gave a chance for epithelium to develop. That scheme works. I have done it now for the fourth time, and one of my associates, calling me to assist him in a difficult icteric case, repeated it successfully for the fifth time. The practical hint is, to follow the suggestion of Willy Meyer, bring the duodenum as close as possible to the stump of the proximal end of the common duct and keep it patulous until the mucosa can grow to mucosa. While the experience of any of us will not be great in numbers, so simple a resource as that described can be found in any operating-room.

Dr. I. J. Strauss, Chicago: In 1912, when I reconstructed ureters from the fascia lata, I got a patent ureter. Epithelium will grow on any medium. You cannot prevent epithelium from growing over a hollow viscus. As to end results, experimentally from the bile duct work, success is due entirely to technical skill. If you take a fascial transplant uppermost, then the hydrostatic bile will distend the tube. Dr. Davis is correct. When I did ureteral work I did bile operations and put a stone into the duct. Then the hydrostatic action caused stricture, and you take out the stone and you have no stricture whatever. This shows that the bile within the common duct is under a very low pressure, and consequently there is always a constriction. If we have high hydrostatic action, we would have no pressure, and these cases of reconstruction of the bile duct would be a success.

Dr. J. Shelton Horsley, Richmond, Va.: The pathology of a biliary fistulous tract is intimately connected with such reconstructive work. Of course, the fistulas that do not close impress us. What is the proportion of external biliary fistulas that do not close to those that do? Exceedingly small. If they do not close we know the reason; usually some obstruction to the bile lower down. The Sullivan operation is as much a transplantation as when a vein or fascia is used and has the advantage of a pedicle for bland supply. Sullivan's procedure has the additional advantage, too, of using tissue in the neighborhood, which has some immunity to the irritating effects of the biliary discharges; but a free transplant is not so well nourished, has no immunity to the irritating discharges, and will eventually contract. The ideal method is to unite the stump of the duct to the submucosa of the duodenum. Dr. Sullivan has authorized me to say that he is in no way responsible for the T-tube. In pulling it out it causes too much damage.

Teach Health to the Children.—Since 90 per cent. of our American children leave school at or before the eighth grade, public health must be taught in the grades if the majority of the population is to be reached.—*Minnesota Public Health Association Journal.*

HEMOPHILIA

EXPERIMENTAL DATA BEARING ON THE EFFECT OF GLYCERINIZED EXTRACTS OF VISCERAL HEMOPHILIC TISSUE ON THE COAGULATION TIME OF BLOOD *

HARRY LOWENBURG, A.M., M.D.
AND
A. I. RUBENSTONE, M.D.
PHILADELPHIA

Inasmuch as the active etiology of hemophilia remains one of the unsolved mysteries of medicine, and inasmuch as medical science affords us no remedial agent which will permanently eradicate the disease, the investigations to be recorded were undertaken with the hope that some new information with reference to the cause of the remarkably slow coagulative property of the blood in hemophilia might be provided. The opportunity to conduct these investigations came to us by reason of the death of a 6 year old lad, who presented the classical family history of this disheartening affection. He had been admitted to the pediatric service of the Mount Sinai Hospital of Philadelphia on several occasions. Each time profuse hemorrhage had followed the slightest trauma to skin or mucosa. Usually he bled from the tongue, mouth or lips—the result of teeth bites from falls. The slightest pressure would produce extensive subcutaneous ecchymoses. At no time would the bleeding cease spontaneously or by the use of ordinary measures. Horse serum or the direct injection subcutaneously of freshly drawn human blood was always necessary to control the bleeding. The anemia following one of these attacks was always profound, and frequently he would become highly toxic following an injection, presenting hyperpyrexia, delirium, urticaria and other evidences of the intracirculatory destruction of foreign protein. Once the bleeding ceased, however, his color and animation would return with amazing rapidity. His father did not bleed, nor did his mother, nor his sister, but his brother, who even now is a patient under the care of one of us (Lowenburg) at the Mount Sinai Hospital, just recovering from a severe hemorrhage following a slight trauma on the forehead, and which required intravenous transfusion to control it, frequently has attacks of bleeding. There is no history of consanguinity. His maternal uncle is a bleeder, having required intravenous transfusion to control what appeared to be spontaneous hematuria. This occurred on two occasions and almost cost the patient his life. Another maternal uncle bled to death. Thus it is seen that we are dealing with a typically classical case of hemophilia. Our patient died at the Mount Sinai Hospital following uncontrollable intestinal hemorrhage of unknown origin.

Assuming that the blood of hemophiliacs does not come in contact with extravascular tissues (skin, muscle, fascia, etc.), that the coagulation time under such circumstances is unduly prolonged beyond normal is not the subject of professional controversy. Howell's experiment, wherein he showed that hemophilic blood drawn directly into a test tube sometimes consumes five hours in clotting, may be readily verified by repetition. Normal blood is coagulated within from thirty to forty minutes. Hemophilic blood presents no striking abnormal variations in the white and the red cell count and the blood plaques. Various authorities have, however, proposed divergent hypotheses as to the elemental causal factor, some ascribing it to an overabundance of anticoagulative substances and others to a deficiency of procoagulative agents.

---

* Read before the Section on Diseases of Children at the Sixty-Ninth Annual Session of the American Medical Association, Chicago, June, 1918.

Thus Morawitz, as well as Lossen,[1] attributed the defect to a lack of thrombokinase; Weil[2] attributed it to an excess of antithrombin; Wright, to calcium deficiency, while Addis[3] and Howell[4] showed experimentally that there was a lack of prothrombin. Howell, as well as Nolf,[5] found no calcium deficiency, and indeed Lossen proved that adding calcium to hemophilic blood causes no decrease in coagulation time. Howell, furthermore, demonstrated no deviation from a normal fibrinogen content and that the blood of a hemophilic, when brought in contact with the tissues of the same person, is coagulated rapidly. For example, if during venipuncture of a hemophiliac, the technic is faulty, and some blood traverses the subcutaneous tissues before it is drawn into a test tube, the blood will clot in little longer time than normal.

Since all workers are practically agreed that extracts of the external tissues exert a marked influence in diminishing the coagulation time of hemophilic blood, it occurred to us to investigate the effects of extracts or emulsions of the various internal tissues, both from our dead hemophilic patient, as well as from those of an apparently healthy, normal boy who died by accident, and to ascertain the effect of these, if any, on the coagulation time of blood.

Our work consisted in preserving samples of the following tissues: brain, thyroid, heart, liver, kidney, suprarenal, pancreas, spleen, muscle and bone marrow.

PREPARATION OF TISSUES

The tissues were cut into very small pieces, and washed in running water for about three hours to rid them of as much blood as possible. They were then ground in a mortar with three times their volume of physiologic sodium chlorid solution and a little glycerin was then added.

To test the effect of these tissue extracts on coagulation of blood, advantage was taken of the method outlined by Howell, consisting of first, oxalating blood plasma and then reactivating coagulation in such plasma by the addition of a suitable amount of calcium chlorid. In this way normal blood plasma clots uniformly in from eight to twelve minutes. The effect of the addition of the various tissue extracts to such preparations of plasma was easily ascertained by gently tilting the test tubes and observing closely how long it took the plasma to form a firm coagulum.

Blood from a normal person was drawn by venipuncture into a Lüer syringe and at once run into a test tube containing a solution of sodium oxalate in physiologic sodium chlorid solution, so that the oxalate was present in about 0.12 per cent. of the entire volume. The oxalated blood was then centrifuged and the supernatant yellowish green plasma pipetted off. The clotting of the plasma was reactivated by adding calcium chlorid as follows: 0.5 c.c. of oxalated plasma was placed in each of five test tubes, and to these were added in series of 0.1, 0.2, 0.3, 0.4, 0.5 c.c. of 0.5 per cent. solution of calcium chlorid, and the coagulation time observed in each test tube to ascertain which amount of calcium chlorid caused the quickest and most uniform coagulum. After several repetitions of this test 0.35 c.c. were found to be most efficient, and with this amount the plasma clotted in eight minutes and forty seconds. Any amount less or more than 0.35 c.c. caused slow, uneven, or no coagulation at all.

Into each of three test tubes were placed 0.5 c.c. of oxalated plasma, one drop of the tissue emulsion and 0.35 c.c. of the calcium chlorid solution. The tubes were closely observed and frequently gently tilted to determine the coagulation time. This procedure was carried out with every type of tissue studied, both hemophilic and normal, together with controls of calcium and plasma alone, glycerin alone, and with thromboplastin-Squibb and that prepared in our own laboratory. These reactions were repeated several times and corresponded with the result shown in the accompanying table.

COAGULATION TIME OF PLASMA AND CALCIUM AFTER ADDITION OF TISSUE

	Hemophilic		Normal	
Extracts	Min.	Sec.	Min.	Sec.
Brain	4		3	
Thyroid	10	30	4	
Heart	4	15	4	30
Liver	9	45	5	
Kidney	4	20	3	40
Suprarenal	4	30	3	10
Pancreas	6	30	4	
Spleen	6		5	
Muscle	5		3	15
Bone marrow	6		4	25
Controls				
Oxalated plasma	No coagulation			
Plasma and calcium			8	40
Glycerin			8	30
Thromboplastin			2	(Squibb)
			2	20(Ours)

RESULTS

It will be noted that the normal tissue extracts uniformly accelerate the coagulation time of the calcium plasma, and that most of the hemophilic tissues with the exception of thyroid and liver seem to exert almost the same influence on coagulation. Thyroid gland and liver not only caused a prolonged coagulation time, amounting to two and one-half times the corresponding normal tissues, but actually inhibited the action of the calcium added to the plasma, so that the coagulation of the calcium plasma was prolonged almost two minutes.

These observations were repeated with uniform results, and though admittedly limited to the tissues of one hemophiliac, yet they are strikingly significant, in that there is a possibility that the thyroid and even the liver may secrete an antithrombic substance or enzyme which may be in part, if not principally, the cause of the deranged coagulative mechanism of hemophilic blood. These observations are recorded with the purpose of stimulating further investigation along similar lines, hoping to localize the offending principle causing this now so-called idiopathic disease.

CONCLUSIONS

1. Not only the external tissues, but also the various other tissues of the normal body accelerate blood coagulation.
2. Hemophilic tissues, excepting thyroid and liver, have the same general effect on coagulation as normal tissues exert.

ABSTRACT OF DISCUSSION

Dr. William Weston, Columbia, S. C.: In the *treatment of* these purpuric conditions, it may be well to *keep in mind* the marked effect that fresh fruit juices have on the coagulation of the blood. For instance, we know that in scorbutus fruit juices assist markedly in the coagulation of the blood.

RECENT STUDIES IN THE ANATOMY AND PHYSIOLOGY OF TENDONS

THEIR APPLICATION TO THE TECHNIC OF TENDON OPERATIONS *

LEO MAYER, M.D.

NEW YORK

My interest in tendons was first awakened in the year 1912, when, while I was acting as *volunteer in* the clinic of Professor Lange, the problem of preventing postoperative adhesions was assigned as an experimental study to Dr. Henze of New Haven and to me.

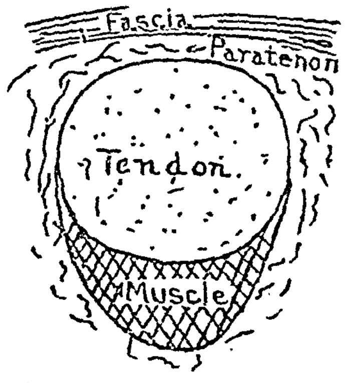

Fig. 1. — Cross-section (diagrammatic) through the tibialis anticus tendon 1 inch above the upper pole of the sheath.

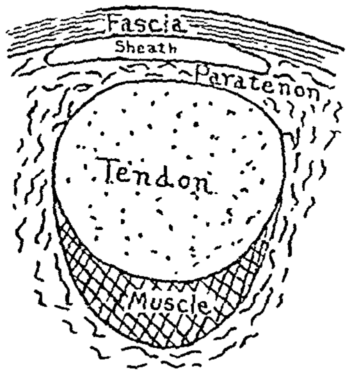

Fig. 2. — Cross-section (diagrammatic) through the tibialis anticus tendon at the level of the upper pole of the sheath.

The problem was one of great importance in Lange's eyes, since, despite his experience in 2,000 operations, the results were frequently impaired by adhesions developing subsequent to the transplantation.

It is, of course, self-evident that the function of the tendon as a means of transmitting the contraction of the muscle to the skeleton is completely inhibited by a single strong adhesion in the same way as the rope of the derrick cannot glide if clamped at a single point. In the course of our experimental investigations, which were conducted chiefly on rabbits, we utilized all manner of membrane, thin tubes of rolled silver, petrolatum, bismuth paste, fascia, peritoneum and a vein as a means of ensheathing the tendon. None of these substances, however, prevented the development of adhesions; in fact, with the exception of the Cargyle membrane, more adhesions were present after their introduction than in control experiments in which nothing was used. Finally we followed the suggestion of Biesalski and utilized the *sheath* of the paralyzed tendon as a physiologic pathway for the transplanted tendon; that is, one tendon was withdrawn from its sheath, cut away from the paralyzed muscle, and the substituting tendon drawn downward by *means* of a guide suture so as to occupy exactly the position of the original tendon. *In all* of the cases observed there was complete absence of adhesions, even when the limb was immobilized for thirty days subsequent to the operation.

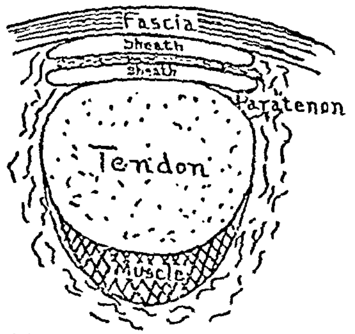

Fig. 3. — Cross-section (diagrammatic) through the tibialis anticus tendon one-half inch distal to the section shown in Figure 2.

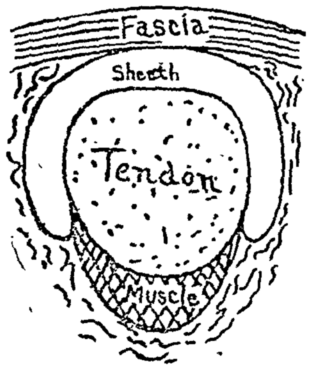

Fig. 4. — Cross-section 1½ inches distal to the section shown in Figure 3.

This clear cut evidence in favor of Biesalski's *method* indicated to me the importance of coordinating the operative technic with the physiology of the structures involved. Just exactly as the normal relationship between tendon and sheath should be maintained, so, too, the normal fascia relationship, the normal tension and the normal fixation of the transplanted tendon should be made as nearly like the normal as possible. When, however, I tried to follow out this line of thought, I found that our knowledge of the physiology and anatomy of tendons was entirely inadequate for the purpose. No one had as yet considered the nature of the gliding mechanism of tendons. In no book, physiologic or surgical, had the subject of tendon tension ever been brought up for discussion. Despite the thousands of tendon operations, some of the simplest facts relative to their anatomy had never been investigated. It was necessary, therefore, before any comprehensive operative technic could be formulated, that these fundamental questions be investigated. The work was conducted by research on the cadaver, animal experimentation and observations on human beings.

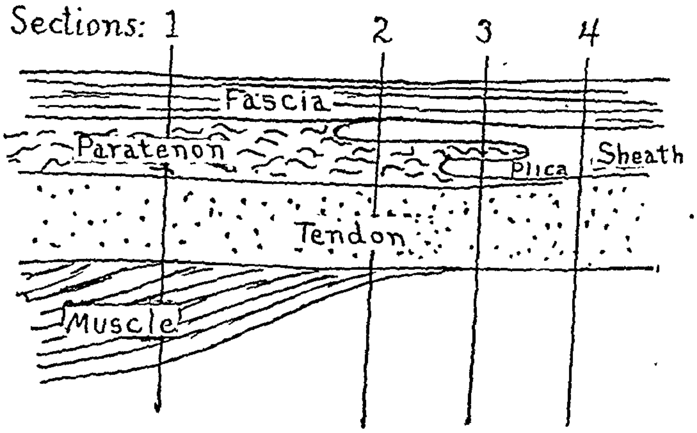

Fig. 5.—Longitudinal section (diagrammatic) of the tibialis anticus tendon, to correlate the preceding cross-sections. Note that the paratenon is prolonged downward into the sheath as a loose fold—the *plica*.

I can best introduce the subject of the anatomy of tendons by a series of cross-sections showing a tendon at various levels above and within its sheath. The first (Fig. 1) shows the tendon about 1 inch above the upper pole of the sheath; note that between the fascia and the tendon is a distinct gap not described in the textbooks. This space is filled with a peculiarly elastic tissue, consisting essentially of fat cells and elastic fibers. This tissue completely surrounds the tendon and the lowermost muscle fibers, and by means of its elasticity allows the tendon to glide freely to and fro beneath the rigid fascia. How great this elasticity is can be seen by incising the fascia and lifting the tendon out of its bed. It will then be seen to stretch from 5 to 7 cm. without rupture of its fibers. It is the important tissue in the gliding mechanism of the tendon; and in every operation on the tendons its presence must be recognized and due emphasis laid on conserving its function.

---

* Read before the Section on *Orthopedic Surgery* at the Sixty-Ninth Annual Session of the American Medical Association, Chicago, June, 1918.

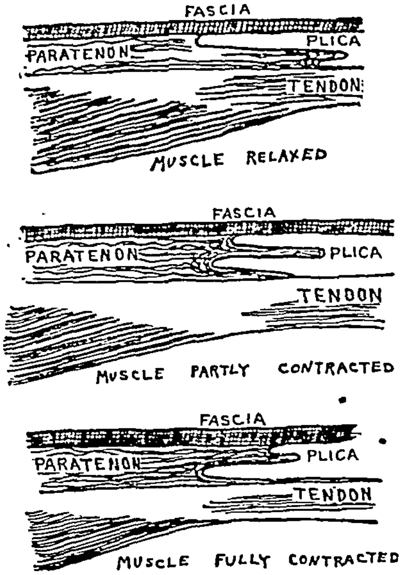

Fig. 6.—Diagrams representing the changes occurring in the form of the sheath during the contraction of the muscle and the consequent gliding of the tendon. Note that the deep pocket of the sheath between plica and tendon increases markedly in length, allowing the tendon to move upward without rupture of the sheath wall.

The next section (Fig. 2) is taken through the upper pole of the sheath. The significant fact is that the gap representing the tendon sheath does not develop between the fascia and the tendon, but between the fascia and this gliding tissue, which I shall henceforth term the "paratenon."

In the next section (Fig. 3), which lies about half an inch distal to the preceding, the sheath is seen to be divided into two portions by a transverse band, the tissue of which is microscopically identical with the paratenon.

In the fourth cross-section (Fig. 4), about 1½ inches distal to the preceding, the tendon sheath is interposed between fascia and tendon and is seen almost to surround the latter. A longitudinal section (Fig. 5) enables us to correlate these four cross-sections. It is evident that the paratenon is prolonged downward into the sheath as a tonguelike structure. The significance of this is appreciated only when the muscle contracts and the tendon moves upward; then it is seen that a kind of invagination occurs (Fig. 6). The deep pocket of the sheath becomes much elongated, thus allowing the tendon to glide, without destroying the continuity of the sheath wall. The essential, of course, is the elasticity of the paratenon which allows this degree of stretching.

By means of simple experiments on dogs the normal tension of tendons was accurately determined. The method consisted in the division of the tendon shortly above its insertion. The tendon ends separated for a distance of from 1 to 2 cm. because of the tension to which they were subjected by the muscular pull; by means of a recording instrument, the proximal tendon stump was pulled downward until brought into apposition with the distal. The degree of force represented the tension to which the tendon was subjected. The figures varied markedly, according to the varying conditions of the experiment; but one fact remained constant, irrespective of the size of the animal or the strength of the muscle: when under anesthesia, the limb was held in such a position that the origin of the muscle and its point of insertion were brought as near together as possible, then the tendon tension equaled 0; in other words, with the tibialis anticus divided and the foot held in the position of calcaneovarus, then under anesthesia the two tendon ends came into exact approximation without the use of any force whatever. This simple physiologic fact is readily applicable to tendon transplantation. The normal tension is restored by holding the limb in such a position as to approximate the origin of the muscle and the new site of tendon implantation.

I can best illustrate the application of the physiologic principle by outlining a typical tendon transplantation; for instance, the transfer of the extensor proprius hallucis for the paralyzed tibialis anticus. The first incision exposes the insertion of the paralyzed tendon. The tendon itself is slit longitudinally and the subjacent bone is traumatized. Against this traumatized surface the transplanted tendon is to be brought since the resulting osteogenic activity of the periosteal cells anchors the transferred tendon firmly in place.

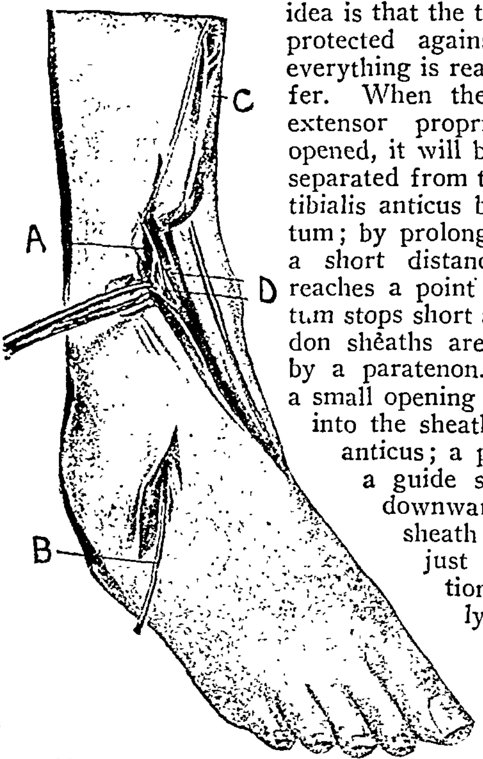

Fig. 7.—Typical physiologic tendon transplantation—transfer of the tibialis anticus for paralytic clubfoot. The probe passing through the sheath of the extensor longus digitorum emerges at the insertion of the peroneus tertius and serves to draw the tibialis tendon downward through the sheath of the paralyzed evertors. *A*, retracted fascia; *B* to *D*, probe passing through sheath of extensor longus digitorum; *C*, tibialis anticus.

The second incision runs along the extensor proprius hallucis. Not the entire tendon but only the upper portion is exposed at first. The idea is that the tendon should be protected against drying until everything is ready for its transfer. When the sheath of the extensor proprius hallucis is opened, it will be seen that it is separated from the sheath of the tibialis anticus by a fascial septum; by prolonging the incision a short distance upward one reaches a point where this septum stops short and the two tendon sheaths are separated only by a paratenon. At this point a small opening is made directly into the sheath of the tibialis anticus; a probe containing a guide suture is passed downward through the sheath and emerges just over the insertion of the paralyzed tendon. By means of this guide suture, the extensor proprius hallucis tendon, which is rapidly freed, is drawn downward through the sheath of the tibialis anticus and anchored firmly in the bed already prepared for it. In fastening it, the foot is held in the position of calcaneovarus and the tendon is pulled on with just enough force to render its course a straight one. Immobilization should not be continued more than three weeks because by that time firm union has occurred. The patient is then allowed to exercise the transplanted tendon, and three weeks later to walk with the transplanted tendon protected from undue tension by an appropriate splint.

The therapeutic results achieved by this method, in the 250 cases in which the operation has been performed in the last three and one half years, have been unusually gratifying.

This brief summary of the principles underlying the physiologic method indicates only in a rough way its application to the treatment of poliomyelitis and paralysis due to gunshot injuries. For further details the reader is referred to my book[1] and to a series of articles published in *Surgery, Gynecology and Obstetrics*.[2] Experience since that time, although it has altered some details, has confirmed me in the view that this method of tendon transplantation offers a valuable means of helping our patients.

149 West Seventy-Ninth Street.

ABSTRACT OF DISCUSSION

Dr. Arthur Steindler, Iowa City, Iowa: I wish to emphasize the importance of the physiologic method of tendon transplantation. Dr. Mayer said something about the clinical results. I can corroborate his statements by my own results, although they were not obtained entirely by his method. I made use of the principles mentioned in a series of about forty cases. The conclusion I can draw is that if the physiologic conditions are observed carefully, if the tendon sheath is either left unharmed, as he does, or reconstructed, as I am doing, according to an earlier suggestion of his, for which I am glad to give him credit; and, furthermore, if the vitality of the tendons is not endangered, and that is the only point, there is no failure of the tendon to work. I mean that it will act from a biologic point of view. I made a survey of my cases and found that it acted in almost every case, barring some cases of infection. With regard to the functional value, it acted functionally satisfactorily in 80 per cent., which is absolutely the converse of what I had found before using this method. One thing which makes me a little doubtful is the question of the dissociation of function. I saw a case in which a tendon transplantation had been performed several years previously and, I believe, successfully, because the tendon acted. After seven years it was, however, impossible for the patient to dissociate function between the two peronei tendons.

Dr. Ethan H. Smith, San Francisco: I should like to emphasize one point, and that is the outcome of tendon transplantation when there is infection. Its importance is well known to the orthopedist, but for the benefit of the general surgeon who is going to do tendon work as the result of military requirements, this point should receive particular attention. Infection is not always absent when a wound is apparently healed; we should be very certain that there is no latent infection before attempting any work on the tendons, because there is nothing that makes so complete a wreck as an infected tendon.

Dr. Charles M. Jacobs, Chicago: In tendon transplantation two important points must be considered: first, the technic, and second, the selection of muscles. In his demonstration Dr. Mayer used the extensor hallucis pollicis to take the place of the tibialis anticus. Notwithstanding the correct technic, the result would prove a failure, because a weak muscle cannot take the place of a strong one. In my opinion, many failures of tendon transplantation are due to the fact that we do not sufficiently consider this fact.

Dr. M. A. Bernstein, Chicago: I have carried on experiments for one year on tendon transplantation, following the technic of Dr. Mayer as closely as possible. My findings were as follows: In transplanting tendons into the sheath of other tendons there followed a traumatic inflammatory reaction, manifesting itself in infiltrative and proliferative change in the endothelial lining of the sheath. This inflammatory reaction depended on the amount of trauma of the tendon and the amount of adhesion, varying with the duration of immobilization of the limb. The microscopic findings are as follows: A proliferation of cells and an exudation of blood into the sheath, with fixation to the tendon to the peritendineum externum. I believed that adhesions, if permitted to organize, would produce ultimate fixation of the tendon. So we carried on experiments along different lines, transplanting the tendon with the sheath and the surrounding fascia, and made examinations varying from eight to twenty-one days after operation. We found, in the cases in which we transplanted the tendon with the sheath and surrounding tissue, that the proliferative change was not so extensive as in the other experiments. Even if there occurred a slight infection of the limb, the infiltrative change took place in the surrounding tissue, but did not extend down to the sheath. The question, therefore, comes up whether the sheath is essential in the transferring of tendons, and whether, if the tendon is transplanted without the sheath, through the sheath of another tendon, if the trauma brought about by rubbing the tendon over the wall of the sheath does not set up a traumatic inflammatory reaction with subsequent adhesions.

Dr. Leo Mayer, New York: Dr. Steindler and I disagree on only one point. He believes that the tissue which connects the tendon with the bone within the sheath, and through which the blood vessels run to the tendon (the mesotendon), should be kept intact in order to maintain the life of the tendon. Of course, it is a good thing to do this; but it is not absolutely necessary, because I have had a chance to observe that the tendon retains its vitality even when these blood vessels are divided. Of course, absolute adherence to physiologic principles in the other steps of the operation is required in order to secure success. The tendon must not be allowed to dry, and the time of exposure must not be more than half a minute. If everything is ready beforehand for the transfer of the tendon it is possible to accomplish this. The tendon gets enough blood vessels through the lower fibers of the muscles to keep it alive, since there is abundant anastomosis within the tendon.

Regarding the transplantation of the peroneus longus, I think that that is the best operation for paralytic valgus, since it converts a strong everter into an inverter of the foot. The trauma is more than offset by the function we secure.

Regarding infection, I endorse what Dr. Smith said. Never operate when there is infection. In the case of gunshot wounds, one should wait at least four months after the injury before operating.

In regard to the selection of the tendon, the point of Dr. Jacobs is well taken. Be very careful to select the right tendon. Do not send a boy to do a man's work. The extensor proprius hallucis should be transplanted for the tibialis anticus only when a strong tibialis posticus is present.

Dr. Bernstein's reports are exceedingly interesting, and I am glad that experimental work is being done to find out further details concerning the physiologic method. There is a certain amount of inflammatory reaction subsequent to the operation. If you draw a tendon down through the sheath of another tendon, there is bound to be some rubbing; but if you are careful it is not excessive. If you fix the tendon effectively you can begin active motion of the muscle three weeks after the operation and easily tear any adhesions that are forming. This occurred in one of my patients.

In operations at the knee there is no opportunity to use the sheath method. There are no tendon sheaths at the knee joint, but we can utilize physiologic principles. In the first place, we can maintain the normal tension of the tendon. The technic of doing this is simplified by inserting a few sutures in the quadriceps tendon which pull the patella upward. In the second place, you can render the course of the tendon as nearly normal as possible by not interfering with the paratenon, which surrounds the tendon. In these two respects the operation differs from that previously performed.

THE BACTERIOLOGY OF MEASLES[*]

LUDVIG HEKTOEN, M.D.
CHICAGO

Many attempts have been made to find the cause of measles and to study the bacteria that produce its complications. It may be of interest to review this work now, and for the sake of clearness of presentation the chief results may be discussed briefly under the headings of protozoa, miscellaneous, bacilli and cocci.

PROTOZOA

Bodies having some resemblance in form to protozoa have been observed in measles. Behla[1] believed that he could see such bodies in the blood; Doehle[2] described peculiar bodies in the leukocytes; and in blister-fluid Rosenberger[3] discovered minute refractile bodies with a rapid darting motion. Little if any significance can be assigned to the observations by Behla and Rosenberger, because they have not been confirmed and extended. Doehle's bodies do not appear to be at all peculiar to measles, being present in a wide variety of conditions (Glomset[4] and others).

MISCELLANEOUS

Under the head of miscellaneous come observations so fragmentary and inconclusive or made with such comparatively crude methods that the results now seem to have little or no value. Keating[5] states that Formad and he saw many micrococci in the blood in malignant cases of measles, during life as well as after death, the cocci being free and also within leukocytes. I place here the micrococcus which Manfredi[6] obtained from measles pneumonia and which caused "progressive lymphomas" in animals; and also the bacillus which Canon and Pielicke[7] in 1892 found in stained preparations of the blood, sputum, and the nasal and conjunctival secretions of fourteen measles patients. They regarded this bacillus as the cause of measles. It was an unevenly staining bacillus, gram-negative, variable in size, and though often present in large numbers, it was not obtained in pure culture. At about the same time Czaikowski[8] found in measles blood a similar bacillus, which he was able to cultivate, however, the colonies being like dewdrops and coalescing; but his work has not been confirmed. Combas and Giarrè[9] were unable to detect any microbes in measles blood with the methods used by Canon and Pielicke; Pacchioni[10] also failed; and others soon expressed doubts as to the value of this work.

Ostrovsky[11] cultivated an ovoid coccus or short bacillus, gram-negative, from the blood, saliva, eye and nasal mucus in measles.

In the spots in measles and in the nose, and occasionally also elsewhere, Mayer[12] found a small gram-negative bacillus, mostly in pairs, not pathogenic for animals, and forming small fluorescent colonies on agar. Mayer regarded this bacillus as a secondary invader.

In sections of lungs with measles pneumonia, Kuleysha[13] found a small bacillus, which, when injected into the blood of animals, caused changes in the lungs like those in measles. He believed that this bacillus was the cause of measles, and that pneumonia is a part of the disease, not a secondary complication.

From the blood in one case of measles von Nissen[14] cultivated a gram-positive bacillus which he called *B. roseus* because it formed red colonies.

Cannata[15] is said to have found a number of different kinds of bacteria in bronchopneumonia in measles, *Micrococcus tetragenus* and *Staphylococcus albus* being the most frequent.

Borini[16] cultivated a small, thin, gram-negative bacillus from the blood, bronchial mucus, and the conjunctiva of children at the height of the fever in measles. This bacillus grew best in vacuum cultures, forming punctiform, transparent, grayish white colonies which gradually coalesced; it caused bronchopneumonia and general invasion on tracheal, pleural and peritoneal injection of rabbits. It was pathogenic also for dogs. No further reports about this bacillus have appeared.

Lesage,[17] in 1900, described a very small, gram-negative micrococcus, which grew well on bloodless agar, and which he obtained from the nose and throat, less often from the blood, in measles.

Gundobin[18] cultivated a bacillus from the blood in sixty of sixty-four cases of measles and claimed good results from the serum of goats and horses injected with this bacillus. Ivanoff[19] described a short, motile, gram-negative, unevenly staining bacillus in the blood and mucous secretions in measles.

A few years ago Costa[20] announced that in eight consecutive cases of measles he found a blastomyces in the blood, but nothing further has been heard of it.

BACILLI

The principal bacilli that have been described in connection with measles may be grouped roughly as diphtheroid and as influenza or influenza-like bacilli.

Diphtheroid Bacilli.—Barbier[21] found the blood sterile, but in the conjunctival secretion he found a bacillus like the diphtheria bacillus, sometimes alone and sometimes associated with other bacilli. In the mouth and nose he noted mostly streptococci. Here belongs probably also the bacillus with club shaped and irregular forms described by Arsamasskoff[22] in the blood, the throat, the eye, and in pneumonic foci in measles.

Zlatogoroff[23] made cultures of the blood of twenty-four patients at the height of measles, inoculating from 25 to 150 c.c. of liquid medium with about 1 c.c. of blood, and in the cultures from seventeen there grew a thick gram-positive bacillus with rounded ends and arranged usually in pairs or small groups. Subcultures do not seem to have been successful. In a few instances similar bacilli were seen in stained preparations of the blood. The results of injection of the cultures into animals were not definite. From the conjunctival secretion Zlatogoroff usually obtained what he calls the xerosis bacillus and a similar but smaller gram-positive bacillus.

In the course of a study of the pneumonia of measles, Ciaccio[24] found a gram-positive, unevenly staining bacillus in sections of the lymph nodes, the spleen, the lungs and other organs of eight patients. In the lungs were also cocci, notably what he regarded as pneumococci.

Armand-Delille[25] reports the recovery of diphtheria bacilli or diphtheroids from the throat in about 42 per cent. of small children with measles. He states that the bacilli were rarely virulent, and that when virulent there was nearly always a membrane present.

Influenza Bacilli.—From about 1899 to about 1907 there appeared several reports which indicate that at least under certain circumstances influenza or influenza-like bacilli frequently occur in measles. In 1899, Paltauf[26] demonstrated the presence of influenza bacilli in bronchopneumonic areas in measles, calling attention at the same time to the presence also of cocci (pneumococci and streptococci). Albrecht and Ghon[27] noted the same thing a little later, and Giarrè and Picchi,[28] Jehle,[29] Süsswein,[30] Giarrè and Carlini,[31] Pacchioni and Francioni,[32] and Davis[33] followed with more extensive observations. In measles patients, Pacchioni found hemolytic bacilli in the eye, in suppurative arthritis, meningitis and pleuritis, and also in the heart blood after death. Giarrè and Picchi, found a minute gram-negative bacillus, which grew only on blood agar and best on pigeon blood agar, in the bronchial mucus and the conjunctival secretion in measles. Hiarri[34] examined the blood in measles with negative results, but in the eye he found an influenza-like bacillus and a diplostreptococcus pathogenic for white mice. He found the influenza-like bacillus also in the bronchial mucus of eight cases.

It may be of interest to note here that before any of these observations had been made, Cornil[35] found a great number of small bacilli as well as cocci in the lungs of an infant that died from bronchopneumonia consecutive to measles and whooping cough. Thaon[36] also found bacilli and cocci in pairs and short chains in measles pneumonia, the cells in the alveoli being filled with them; he regarded these organisms as the cause of the bronchopneumonia that was present in every measles patient dying in a certain hospital the air in which he believed was contaminated.

Jehle found the bacillus of influenza in the eye commonly and in the blood after death in fifteen of twenty-three cases of measles, and also but not so commonly in scarlet fever and in varicella. He believed that these diseases in some way favor general infection with the influenza bacillus when it is present on the tonsils or in the bronchial mucus, and that this form of secondary infection may cause a high mortality. Süsswein found the influenza bacillus in the nose of measles patients during life, and after death in the bronchial contents and the pneumonic and pleural exudate; and as influenza infection appeared to him to be a frequent and dangerous complication of measles, he recommended separation of patients with mixed infection from those with pure measles, in order to lessen the number of deaths. Liebscher[37] also found influenza bacilli in measles, during life and after death, though not so often as Süsswein; but he notes that the patients that had the bacillus in the nose gave a higher death rate than those that did not have it.

Continuing their work, Giarrè and Picchi found a hemophilic bacillus as the predominating organism in the conjunctival, nasal and bronchial secretions. It was a short, thin, gram-negative bacillus, growing only on agar with pigeon blood. In seventeen instances in which the blood was examined before or after death, this bacillus was found only three times. Later Giarrè and Carlini made a special study of the blood for this bacillus in twenty-four cases of measles, mostly in the eruptive period, and in six children that had had measles; the cultures from the latter were all negative, but in twenty-one of the measles patients the cultures were regarded as successful, although subcultures were obtained only twice. In stained preparations of the centrifugate of the laked blood, they report that they saw the bacilli in practically every instance of measles. In seven instances the bacillus in question, which they regard as the same as that described by Giarré and Picchi[28] in 1900, were grown from the eye in measles and studied in subcultures. They grew the pneumococcus from the blood three times and observed it in stained blood specimens five times.

Pacchioni and Francioni, however, failed to grow hemophilic bacilli from the blood in measles. They examined twenty-five patients, mostly just before the eruption, inoculating blood drawn from the veins on various mediums. A hemophilic bacillus appeared only once, and that was in the case of a patient who later died of bronchopneumonia. In seven instances, cultures developed of a large, gram-negative coccus, shaped like the coffee-bean, and regarded as *M. catarrhalis*. They also failed to find bacilli in centrifugates of laked measles blood, using the same method as Giarrè and Carlini, and they suggest that the latter probably erred in their interpretation. As they found the blood sterile in the early stages of measles,

Pacchioni and Francioni hold that in uncomplicated measles there probably are no bacteria in the blood, and that in the instances in which bacteria actually were cultivated from the blood it concerned secondary infections due to a weakened resistance, hemophilic bacilli seeming to be the most frequent cause of such infection.

Reisz and Gins[38] observed influenza bacilli in the blood in a nursling with bronchopneumonia after measles.

In this country, Davis seems to have been practically the only one who has studied the question of the relation of the influenza bacillus to measles. He examined twenty-two uncomplicated cases, making cultures and smears from the sputum, and when sputum was not obtainable, from throat swabs. Only one examination was made in each case, but all the examinations were made during the eruptive stage, cough being present as a rule. Influenza-like bacilli were isolated in pure culture in thirteen of the twenty-two cases; in four such bacilli predominated, but sometimes there were only very few. Streptococci and pneumococci were present on every plate, the latter being the more numerous. Davis found influenza-like bacilli in the throat of only two of twenty normal persons.

It should be noted, however, that Cole's[39] mouse inoculations with the sputum of measles bronchopneumonia, the main result of which was the recovery of hemolytic streptococci in sixteen of seventeen cases, in eight of the cases also gave *B. influenzae*. Further, that while the sputum cultures in thirty cases all yielded hemolytic streptococci, in thirteen of the cases the influenza bacillus also was found. This bacillus was present too in the lungs and the heart blood after death in some cases together with streptococci, but these cases did not seem to differ from others in which only streptococci were found.

The comparative frequency of *B. influenzae* is of considerable interest, and it may be well in the further study of the bacteriology of measles not to lose sight of this bacillus.

COCCI

Streptococci.—The pioneer work on the bacteriology of measles was done by Babes[40] about 1880. In stained preparations of the nasal, conjunctival and bronchial secretions, of the blood of the skin in eruption, Babes found small cocci in pairs and short chains. In one case the blood contained also a short bacillus. In sections of the skin removed during life on the second day of the rash he saw micrococci in the dilated capillaries of the papillae. Agar cultures of the blood from the skin, of lymph nodes, and of inflammatory products of the lungs and pleura, gave streptococci like the streptococci in pus; occasionally the pulmonary and pleural exudate would develop in culture an encapsulated microbe that killed rabbits. In sections of lungs with measles pneumonia, in which Babes described the interstitial lesions recently emphasized again by MacCallum,[39] large numbers of cocci were found. Commenting on these observations, Cornil and Babes discuss briefly the question whether pneumonia may be an expression of a generalized measles; they held that of the bacteria in the lesions consecutive to measles, the streptococcus merited the most attention.

Tobeitz[41] found groups and chains of cocci in and about the bronchi in measles pneumonia.

In sections as well as cultures from bronchopneumonia in measles, Guarnieri[42] obtained streptococci regarded as identical with *Streptococcus erysipelatis.*

Méry and Boulloche[43] found pneumococci in the saliva of 29 per cent. and streptococci in 23 per cent. of young children with measles, these being larger percentages than in the case of well children. They reason that in measles there occurs a specific lesion in the lungs—an enanthem—on the basis of which secondary bronchopneumonia, due to a superficial, descending, respiratory infection, may develop. To guard against this bronchopneumonia, mouth cleanliness is recommended.

After death from measles, Slawyk[44] found streptococci in the blood in fifteen of sixty-eight cases and only two or three other bacteria scatteringly. The streptococcus cases included nine cases of enteritis, two of bronchopneumonia, two of empyema, etc.

Pospischill's[45] contention that streptococcus infection in measles and varicella usually is in reality a septic scarlet fever has not received any notice.

In scarlet fever, measles and other acute infectious diseases, Hlava[46] isolated a streptococcus, which formed a homogeneous capsule when grown on mediums with a high saccharose content, and which he called *Leuconostoc hominis.* Hlava regarded the coccus as different from *Streptococcus pyogenes* and suggested that possibly acute infectious diseases are caused by different forms of this coccus, which he obtained from the throat and nasal secretion of all the eight measles patients he studied and twice from the blood. He found streptococci also in sections of the lungs and of other organs in measles bronchopneumonia.

In forty-five cases of simple angina complicating measles in adults, Simonin[47] found streptococci as the predominating organism in the throat in twenty-five and staphylococci in sixteen. The pneumococcus was found only rarely.

In otitis after measles, Albesheim[48] found streptococci and staphylococci in pure culture and also associated with a gram-positive bacillus.

Schottelius[49] found *Staphylococcus aureus* in the conjunctival secretion of fifty-one cases of eighty examined and also streptococci, but not so often. In the lungs and spleen of children that had died from measles, a streptococcus was found regularly, occasionally associated with other bacteria.

Folger[50] and Eckert[51] each describe two cases of fulminant streptococcus sepsis in measles, such apparently being rare occurrences.

Craig[52] reports an outbreak of measles in a military camp involving eighty-nine cases, in twelve of which bronchopneumonia developed with ten deaths. In nine of ten fatal cases there were empyema and abscesses of the lungs. In all the fatal cases a rapidly growing streptococcus was cultivated from the lungs and the spleen, accompanied in six instances by the pneumococcus, in three by staphylococci, and in one by *B. proteus*. Craig found severe lesions—hemorrhages, focal necrosis, hyaline degeneration—in all the organs, and emphasizes the virulent nature of the infection.

Menschikoff[53] made a systematic bacteriologic study of sputum, nasal mucus, conjunctival secretion and ear discharges and blood in measles. Diplococcal forms predominated in the ear and the eye, and pneumococcus-like bacteria were grown from the blood in nine of sixty-one cases. On hemoglobin-agar plates the sputum gave deep brown colonies of a diplostreptococcus (*Diplostreptococcus brevis*) which he regarded as distinct from the pneumococcus; this being the only bacterium present constantly, he suggested that it may play the same rôle in measles as the streptococcus in scarlet fever. Menschikoff also isolated a gram-negative bacillus which grew only on hemoglobin-agar or blood-agar mediums.

Eyre[54] studied twenty cases of bronchopneumonia in measles and obtained the pneumococcus in pure culture four times, the streptococcus five times, the pneumococcus mixed six times, and the streptococcus mixed five times, mostly the one with the other but also with the staphylococci, influenza bacilli, etc. The examinations were made usually a few hours after death, but sometimes during life on aspirated material.

Lorey[55] seems to have been the first to use blood agar in the study of the bacteriology of measles. He examined the throat and made blood cultures in 150 cases; the tonsils gave hemolytic streptococci and in many cases also diphtheria bacilli and pneumococci; the blood in fifteen cases gave cultures of streptococci and in seven others also pneumococci, colon bacilli, paratyphoid bacilli, etc. In the middle ear discharges there were mostly streptococci. Lorey holds that the streptococcus is the most dangerous invader not only in scarlet fever but also in measles, and that probably the variations in the severity of measles epidemics are due to variations in the spread and invasiveness of streptococci, which may be spread by the hands of nurses, by playthings, eating utensils, etc., as well as by droplets. Lorey recommends that in hospitals children with streptococcus infection be isolated.

Recent observations indicate clearly that the hemolytic streptococcus has been the principal cause of the outbreaks of bronchopneumonia following measles in our military camps during the past year (Irons and Marine,[56] Cole and MacCallum, Levy and Alexander,[57] Cumming, Spruit and Lynch,[58] and Dick[59]). Cole reports that hemolytic streptococci were present in cultures of sputum coughed up from the deeper parts of the respiratory tract in the thirty cases of postmeasles bronchopneumonia examined, and mouse inoculations with such sputum from seventeen cases yielded streptococci in sixteen. Blood cultures during life in fifteen cases gave hemolytic streptococci twice. Of the thirty cases, death occurred in fourteen at least, and in all hemolytic streptococci were found in the affected parts of the lungs and in the pleural exudate in practically pure culture; the blood also usually contained hemolytic streptococci. MacCallum found the abdominal organs free from streptococcal invasion, but in the areas of interstitial bronchopneumonic lesions, which were characteristic of streptococcal bronchopneumonia, streptococci were present on the pleural exudate and in the bronchi, and in the purely lobular pneumonic areas they were often present in amazing numbers in the exudate. It appears as if the streptococcus infection in these cases was less violently virulent than in the cases described by Craig in which there were severe lessions—hemorrhages and necrosis—in the abdominal organs. This difference might be explained as the result of a somewhat greater parasitism on part of the strains concerned in the cases studied by Cole and MacCallum.

That nonhemolytic streptococci also may cause complications of a serious nature in measles is indicated in the report by Lathrope[60] of a series of cases of acute mastoiditis, forty-four of which followed measles (either directly or within a month after dismissal from the hospital), and in which the dominant organism seemed to be of the *S. viridans* type.

How are measles patients infected with hemolytic streptococci? The facts at hand point directly to droplet, contact and dust infection by way of the throat. It appears that hemolytic streptococci may spread easily in military camps and in measles wards when special precautions are not enforced. Irons and Marine found that, during a period of respiratory infections, hemolytic streptococci developed in the throat cultures of about 70 per cent. of healthy soldiers. Levy and Alexander obtained hemolytic streptococci from the throat in 14.8 per cent. of strictly fresh recruits; but in an organization in which most of the men had been in service about six months, the number of streptococcus carriers was no less than about 80 per cent. Of the measles patients admitted to the base hospital of this camp, most of them coming from the organization just mentioned, 77 per cent. were carriers of hemolytic streptococci, and the complications occurred almost exclusively among the streptococcus carriers, bronchopneumonia with empyema due to streptococci being by far the most frequent and the most important. Cumming, Spruit and Lynch report that while 35 per cent. of measles patients had hemolytic streptococci in the throat, this was the case in only 6 per cent. of healthy soldiers. Cole and his associates found that in a measles ward 56.5 per cent. of the patients harbored hemolytic streptococci in the throats as compared with 21.4 per cent. in a ward for patients suspected to be tuberculous. They found the hemolytic streptococcus in the throat of 11.4 per cent. of the measles patients on admission; after from three to five days in the ward in 38.6 per cent. and after from eight to sixteen days in 56.8 per cent. These valuable observations all point unmistakably to the ease with which the hemolytic streptococcus may pass from carrier to noncarrier and in the measles convalescent set up bronchopneumonia and empyema. In connection with this postmeasles streptococcus infection, it is of interest to recall that Tunnicliff found the phagocytic power of the leukocytes for streptococci reduced in the leukopenic stage of measles, and MacCallum notes that in the lung lesions he studied there was not free phagocytosis of streptococci. We know that in measles the tuberculin and other allergic reactions are enfeebled and even suppressed, and it may be that the frequency of streptococcus infection in this disease depends in some degree on reduction in the powers to react against streptococci.

The Tunnicliff Diplococcus.—Using anaerobic methods, Ruth Tunnicliff[61] recently has cultivated a coccus from the blood during the early stages of measles in forty-two of fifty cases, mostly in children.

It appears that at the height of measles, diverse bacteria may develop in cultures of the blood by special methods. Thus Tunnicliff in her series obtained examples of aerobic and anaerobic diphtheroid bacilli, filamentous organisms, spirilla, pigment and spore-forming bacilli, and staphylococci. Similar organisms occur in the throat, nose and eye.

The coccus in question seems to be most numerous in the blood shortly before the rash comes out and to disappear when the rash fades. Aerobic cultures and anerobic fluid cultures gave no results, the best results being obtained with semicoagulated horse serum and with whole blood in ascites glucose agar in the form of shake cultures. As a rule growth would appear in from five to fifteen days at 37 C. In subcultures the coccus may grow under aerobic conditions, when it forms small, greenish, as a rule nonhemolytic colonies on blood agar, the growth on glucose agar being moist and more profuse. A small coccus when first isolated, it passes Berkefeld N filters, but in subcultures it becomes somewhat larger. It is gram-positive and occurs as single cocci, especially as round or flattened diplococci, and in short chains. It ferments glucose, saccharose and maltose, but not inulin, salicin or raffinose.

Tunnicliff has isolated this coccus from the throat in measles, also from the nose and eyes, and in a single instance from the ear. Early in the attack, smears from the tonsils and anterior pillars may show large numbers of diplococci, like those in the cultures, the picture being different from that in similar smears from cases of scarlet fever and of rubella. For this purpose the smears may be fixed with heat, stained a few seconds with carbolgentian violet, washed and dried.

Extensive animal experiments with the coccus or its products have not been made, but it kills rabbits without causing any special changes, and caused leukopenia in a monkey. In regard to its immune reactions, Tunnicliff reports a rise in the opsonic index of the blood serum in measles as the symptoms subside, lasting from one to four days, and at this time the serum also contains complement-fixing bodies in feeble concentration. Tunnicliff and Brown[62] find that specific agglutinins and opsonins develop in the blood of rabbits injected with the coccus, but agglutinin tests are difficult because the coccus clumps spontaneously, and consequently the opsonin test is the best method yet known to differentiate this coccus from other cocci with similar cultural and morphologic characteristics.

Whatever the relation of this coccus to measles, the results just sketched call for further work along various lines.

SUMMARY

From this review it appears that the chief bacteria to engage the attention in connection with measles at present are: (1) the diplococcus found by Tunnicliff in the blood early in the attack and in the throat and nose; (2) influenza bacilli, and (3) hemolytic streptococci. As opsonins and probably other bodies specific for the Tunnicliff diplococcus come into the blood in the course of the measles attack, this coccus must be of some significance, but the exact significance we have still to learn. While hemolytic streptococci seem to predominate overwhelmingly in the bronchopneumonia and other allied acute processes in measles, influenza bacilli are found so frequently in the throat secretions and in lung lesions that doubt arises as to their harmlessness. Hence the part played by these bacilli in measles should be studied further. As hemolytic streptococci may spread rapidly among measles patients, and largely it would seem by droplet and throat infection, the best way at hand to avoid the most serious complication of measles, namely, streptococcus bronchopneumonia, is early isolation of the patient under conditions that protect against infection from persons, including fellow patients, that may harbor streptococci. Such isolation protects against other infections (pneumococcus, influenza bacillus) also. The possible danger of streptococcus infection by way of food should not be overlooked. Finally, it is evident that the immunology of the streptococci concerned, their unity or plurality, their changes in virulence, and other problems require continued investigation.

The Health of Women in Munitions Manufacturing.—Women less than 23 years old are better fitted physically for the heavier work of munitions manufacturing than those further along in years, according to the results of an investigation of conditions in English factories made by Major Greenwood of the welfare and health section of the Ministry of Munitions. The investigation related to about 40,000 employees of eighteen representative factories in Great Britain. It was found that the older women, a large proportion of whom were married, were doubly handicapped by their age and their home duties, when they were employed in the heavy factory work, such as the making of projectiles and shells. In the lighter work, however, such as the making of fuses, cartridges and explosive supplies, these handicaps had little adverse effect on the health of the workers. The difficulty seemed to lie not in the general strain of factory life, but in the moderate degree of actual physical labor required, which taxed the health of the older women far more severely than that of the younger. With a view to prevent wastage in labor and to promote greater efficiency, the author suggests a preliminary medical examination for all women munitions laborers, as well as a redistribution of feminine labor between the two types of factories, so that each woman will have a chance to do the kind of work best suited to her strength.

Military Medicine and Surgery

A STUDY OF DIPHTHERIA CARRIERS IN A MILITARY CAMP

FRANK R. KEEFER, M.D. (Washington, D. C.)
Colonel, M. C., U. S. Army

STANTON A. FRIEDBERG, M.D. (Chicago)
Major, M. C., U. S. Army

AND

JOSEPH D. ARONSON, M.D. (Philadelphia)
Captain, M. C., U. S. Army

CAMP DONIPHAN, FORT SILL, OKLA.

Writers on military hygiene have affirmed that diphtheria has never been of serious importance in the Army, for the reason that it is easily controlled. This opinion is not shared by the officers on duty at the Base Hospital, Camp Doniphan, since their experience has demonstrated that, under certain circumstances, an epidemic of the disease is exceedingly difficult to overcome.

During the early months of 1918 the control of diphtheria, with especial reference to the carriers of the disease, was a very serious problem, which for a long time seemed but little influenced by the strenuous efforts of the staff.

As shown in Chart 1, a few cases were constantly present from October, 1917, but it was not until the latter part of January, 1918, that the disease began to show a marked upward tendency. From that time it persisted, despite the most earnest efforts and carefully devised safeguards, for nearly four months.

During the period cited, 461 cases and 686 carriers of diphtheria were observed. In their study, nearly 30,000 cultures were made and examined.

By the greatest of good fortune, the degree of virulence of the responsible organism was slight. Only three deaths occurred, all as the result of myocardial degeneration, and the individuals concerned were already enfeebled as a result of antecedent disease.

The condition, however, was serious militarily, since it compelled the withdrawal, from organizations engaged in intensive training for war, of more than a thousand men. These were separated from their commands for long periods, since the vital question was not how quickly a person might be returned to duty, but how long before it would be safe for his organization to receive him.

The infection was exceedingly tenacious. The means employed for the control of the epidemic, though in many respects more vigorous than those suggested by authorities on the subject, for a long time barely sufficed to maintain an equality between outgoing and incoming cases.

The intramural situation gave most concern. At a time when but few cases were under treatment, it was discovered that more than half of the twenty-six wards contained carriers, among patients and attendants. Though cultures were made of all in such wards, and infected individuals removed, the next search, at an interval of from five to seven days, was sure to reveal at least as many more who harbored the organism.

The epidemic was finally overcome only when available susceptibles had been segregated, or, in the course of military events, had been transferred elsewhere.

STATISTICAL BASIS OF THIS SURVEY

No attempt is made in this paper to discuss the treatment of clinical diphtheria, its complications or results, as that subject has been thoroughly treated by others. We are chiefly interested in the discussion of the diagnosis, treatment, results and control of the carrier condition and the epidemiology of the outbreak in this camp.

The data for this paper were derived from (*a*) the study of 686 diphtheria carriers and 461 cases of clinical diphtheria; (*b*) the incidence of *B. diphtheriae* in patients admitted to the head surgery section; (*c*) the results of operative treatment in 294 diphtheria carriers; and (*d*) laboratory investigations.

CLASSIFICATION OF CARRIERS

Carriers may be thus classified:

1. Primary carriers: A, transient; B, chronic.
2. Secondary carriers.

A primary carrier is one who has never had clinical diphtheria. In transient carriers the bacilli do not find more than a temporary resting place, the reason being that the nasal passages are normal and the tonsils are quite healthy or have been enucleated. The chronic carrier is one in whom positive cultures are obtained for an indefinite period of time. In some of these individuals the carrier condition is intermittent. Following a series of negative cultures, positive cultures recur at irregular intervals. Reinfection, overgrowth by other bacteria and the fact that the organisms are deep in the crypts and have not manifested themselves on the surface at that examination may be suggested as possible reasons.

The secondary carrier is one who, having recovered from clinical diphtheria, still continues to harbor the germs of the disease.

TABLE 1.—NUMBER OF CULTURES EXAMINED

Year	Month	Positive		Negative	
		No.	Per Cent.	No.	Per Cent.
1917	October	10	52.6	9	47.4
	November	90	22,9	302	77.1
	December	138	7.6	1,684	92.4
1918	January	350	9.2	3,462	90.8
	February	895	18.9	3,855	81.1
	March	1,236	15.3	6,849	84.7
	April	1,451	25.1	4,330	74.9
	May	456	8.9	4,702	91.1
Total		4,626	15.5	25,193	84.5

THE VALUE OF CULTURES

The carrier condition can be determined only by means of cultures. A single negative culture has but little value, as is proved by these figures: Of 294 cases in which tonsillectomy was performed for the relief of the carrier state, cultures taken from the tonsils immediately preceding the operation yielded positive results in 57 per cent. of the cases, and negative results in 43 per cent. Cultures of the tonsils after removal gave positive results in 77.2 per cent of the cases. The fact that negative cultures were obtained in 22.8 per cent. of individuals in whom the carrier condition had been definitely proved emphasizes the necessity for caution in overestimating the value of a single negative culture. In a number of instances a pure culture of *B. diphtheriae* was obtained from tonsils removed from patients who had not been identified as carriers. But these patients had had the disease from four to fourteen weeks previous to admission and had been released on the required number of negative cultures. As is well known, negative cultures may be obtained at times from cases that run the course of typical clinical diphtheria.

The value of nasal cultures is not fully appreciated. That a nasal culture is of great importance is well illustrated by the case of a carrier who was under observation for a period of four and one-half months. Cultures from the nose were much more consistently positive than those obtained from the throat. Tests made on several occasions showed that the organism present in the nose was distinctly virulent for guinea-pigs.

These figures illustrate the returns that may be expected in all types of nasal and pharyngeal carriers. Of 700 cultures from the nose and throat, positive returns from the nose were obtained in 26 per cent. of the cases, while those from the throat were positive in 31.7 per cent.

SYSTEM EMPLOYED IN MAKING CULTURES

On the appearance of a clinical case of diphtheria or of a carrier, the regimental surgeon was requested to have all contacts appear at the regimental infirmary at an hour most convenient to the company commander, usually at 1 o'clock or immediately before a formation. When a second or a third case appeared in the same company, cultures were taken from all members of the organization in order to ascertain if carriers were present.

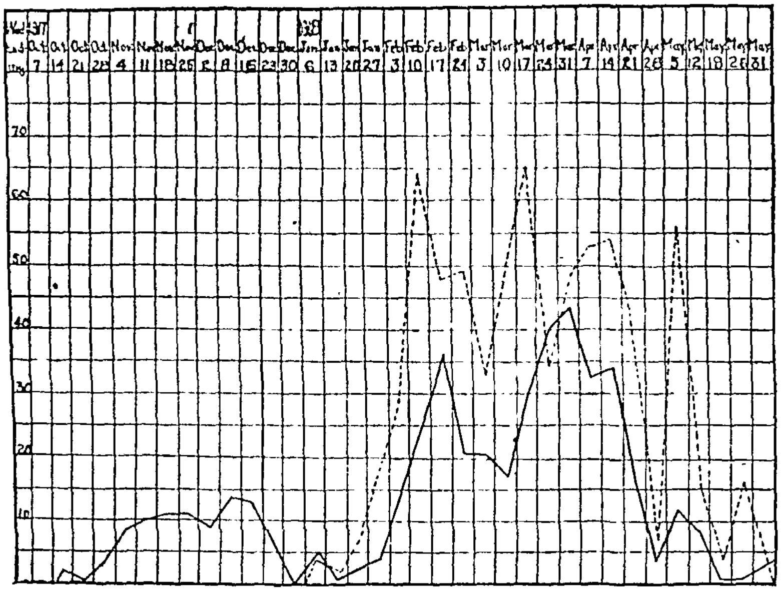

Chart 1.—Weekly occurrence of diphtheria and diphtheria carriers at Camp Doniphan: solid line, cases; broken line, carriers.

The cultures were taken from the nose and throat and planted on Loeffler's medium, one tube being used for both swabs. Tubes were then collected and returned to the laboratory for incubation and examination. Tubes of the medium, together with sterile swabs, were distributed weekly to each regimental infirmary in order that cultures could be promptly taken in all cases of sore throat. The inoculated tubes were then delivered to the laboratory by the ambulances on their regular rounds. After incubation for from eighteen to twenty-four hours, cultures were smeared and stained with Loeffler's methylene blue.

BACTERIOLOGIC DIAGNOSIS

To aid in establishing uniformity in diagnosis, we adopted Wesbrook's classification of *B. diphtheriae*. Those organisms showing the morphology of Wesbrook's Types A, A^1, B, B^1, C and D were considered as being positive. Those that did not show all the characteristics of these types were further incubated for from four to six hours in order to ascertain if they would assume those characteristics.

In the course of this study it was noted that diphtheroids were found more frequently when cultures made from the nose and throat were planted on the same tube. In all doubtful cases, when no definite decision could be made, cultures of the nose and throat were inoculated on separate tubes. In these cases it was frequently found that the throat cultures were negative while the nasal ones showed the presence of suspicious organisms.

No attempt was made to carry out virulence tests as a routine measure, since the large number of cases made it impracticable. In cases of doubtful morphology, and in those cases running a persistent positive course, virulence tests were carried out. Twelve cultures obtained from the nose, eleven from rib resection wounds, and nine from the throat were tested for virulence. Of this group of thirty-two cases, eleven cultures from the nose, two from the rib resection wounds, and nine from the throat were virulent for guinea-pigs. In order to conserve animals, the method advocated by Zingher and Soletsky[1] was used. The culture was isolated, transferred to tubes of Loeffler's blood serum, and, after from eighteen to twenty-four hours' incubation, the slant was washed off with sterile salt solution until a uniform dense emulsion was obtained. Of this emulsion from 0.1 to 0.2 c.c. was injected intracutaneously into a guinea-pig. At the end of from twenty-four to forty-eight hours an area of redness and induration developed at the site of inoculation which, in most instances, went on to necrosis in those animals showing positive reactions.

LOCALIZATION OF ORGANISMS

Every carrier was given a thorough examination in order to localize the affected area. After thorough cleansing of the mucosa, several cultures were made from the superior and inferior regions of each nostril and from each tonsil.

A positive culture from the throat does not necessarily imply that the carrier condition is located in this region, as the bacilli may be carried from the nose or nasopharynx by the inspired air or by the secretions. On the other hand, the bacilli may be carried from the throat to the nose by the expired air or the act of sneezing, and from the resulting positive nasal culture one might infer that the nasal passages were involved. No faith should be placed in a single negative culture, especially in those who have previously shown a positive culture. Conversely, the finding of a single positive culture is not sufficient evidence to justify the diagnosis of carrier, as this may be the prelude to an attack of clinical diphtheria that has not yet had time to manifest itself.

FOCI OF INFECTION

Tonsils.—The presence of a favorable soil for bacterial growth is a factor that determines the persistence of the carrier condition. If necrosis or ulceration of the epithelium covering the tonsils or lining the crypts is present, the bacilli may be found in the tissue beneath the diseased area. The size of the tonsil, per se, is not a factor as a predisposing cause in establishing the carrier condition. The degree to which the tonsil is covered, the extent of surface exposed, lobulation, and the presence of folds or crevices, all have a definite influence on infection of the tonsils by interfering with the evacuation of the crypts. In this study it has been demonstrated repeatedly that acute or chronic pus infections are often associated with diphtheria carrier conditions.

---

[1] Zingher and Soletsky: Jour. Infect. Dis., 1915, **17**, 456.

In order to ascertain the points of localization of *B. diphtheriae* in the tissues, cultures were made from the nose and throat immediately preceding tonsillectomy, and planted on separate tubes of Loeffler's medium. The excised tonsils were received in sterile Petri dishes and delivered to the laboratory. After removal of the surface blood and bacteria by means of sterile salt solution, a sterile swab was inserted deeply in the crypts and then inoculated on Loeffler's medium. From the tonsils found to be infected, almost pure cultures of *B. diphtheriae* were obtained in the vast majority of cases. In most instances the organisms displayed the morphology of Types C and D of Wesbrook's classification. About ten or twelve showed his Types B and B^1, while in five or six cases Type A was found.

In two cases studied, Lieutenant Thorne, M.C., demonstrated the presence of *B. diphtheriae* in the submucosa of a tonsil from the surface of which a pure culture had been previously obtained, thus confirming the work of others.

Nose.—The next location, in order of importance and frequency, is the nose. Acute or chronic infection of the accessory sinuses, ulceration or erosion of the septum or soft tissues, and the presence of dry secretions and gross abnormalities interfering with ventilation and drainage all furnish favorable conditions for the lodgment of the bacilli. In the chronic accessory sinus affections, especially those associated with marked atrophic changes, the prognosis is almost hopeless. It was impossible to discover any particular location within the nose that favored the growth of the bacteria. Washings from the sinuses invariably proved negative. The idea that the mucous glands were the definite points where the bacilli thrived was not substantiated. Tissues removed from the various regions of the nasal passages were sectioned and stained for the organism with results that were entirely negative. In spite of several failures to demonstrate the presence of the organisms, their general distribution throughout the nasal passages justifies the belief that, sooner or later, they will be found underneath the diseased mucous membrane and possibly in the ethmoid cells.

Nasopharynx.—The nasopharynx ranks third in order of frequency as a lodging place for *B. diphtheriae.*

This may be attributed to the presence of ulcerative or inflammatory processes, infections of the posterior ethmoid and sphenoid sinuses, and the presence of hypertrophied adenoid tissue. The size of the latter is not of etiologic significance, as a relatively small amount may harbor the bacilli as effectively as a large mass. The same difficulty has been met in finding the organism in the adenoid tissue that was encountered in the case of the nose.

Wounds.—Wounds may carry the bacilli for an extended period of time. An epidemic of wound diphtheria occurred in two wards occupied by patients who had rib resections for empyema. In one of these wards the diphtheria bacillus was first demonstrated in the wound of a head carrier; this occurred about the middle of March. Five more cases had developed by the end of the month, and twenty-eight occurred in April and ten in May, making a total of forty-four cases. In thirty-three of these cases, *B. diphtheriae* was found in the wound alone, while in twelve the organism occurred in both wound and throat. In thirteen cases the presence of a pseudomembrane and other characteristics of a diphtheric wound were noted. With few exceptions the organism was recovered from granulation tissue, while cultures taken from the depth of the wound were usually negative.

The virulence of the organism was proved by intracutaneous injections into guinea-pigs. In one of two cases thus studied, redness and induration at the site of inoculation was produced after twenty-four hours, and at the end of seventy-two hours local necrosis was well marked. The second pig died within seventy-two hours after an intracutaneous injection of 0.2 c.c. of an emulsion of the culture. At the postmortem examination typical lesions of diphtheria were found.

In several instances the organism was recovered from the skin which had covered over the opening into the chest.

Ears.—In a few cases the bacilli were found in the discharge from acute and chronic suppurative processes of the middle ear.

NONOPERATIVE TREATMENT OF THE CARRIER CONDITION

For the cure of the carrier condition many medicinal agents have been advised, such as sprays, applications, gargles, douches and inhalations. Other agents, acting in a purely mechanical manner (such as kaolin), have been proposed. At various times antitoxins, diphtheria vaccine, antibacillary serum, toxins of *B. pyocyaneus,* and cultures of various living bacteria have been recommended and reported on favorably. From experience derived previous to and during this epidemic, we feel that the value of any local treatment is particularly liable to be ineffective because of the fact that the bacilli are found in the depth of the crypts and beneath the epithelium and are, therefore, untouched by the remedial agent.

In nasal carriers the cessation of the carrier state takes place on the disappearance of the accompanying pathologic condition; therefore, efforts must be directed toward the improvement of the underlying condition.

In the most persistent carriers, local measures were without avail. Various kinds of solutions for irrigation, silver salts, dichloramin-T, crystal violet, and oily sprays were given a thorough trial. It was not difficult to obtain negative cultures while the treatment was being carried out, but when this treatment was discontinued the cultures were again returned positive, and, unless the patients were kept under careful control, it was quite easy to draw inaccurate conclusions regarding the effect of local measures. The harm, of course, results in the release of carriers who are still a menace to their comrades. It must not be construed from what has been written that the affected regions, especially the nose, should not be kept clean, since this is one of the prerequisites for the restoration of the normal functions of the diseased area. At the same time the use of strong irrigating solutions should be carefully governed, for, if used in too great strength, the mucous membrane will be injured to a further degree.

When a wound is involved, it should be dressed frequently in order to keep it as clean and dry as possible, and all granulations should be removed.

OPERATIVE TREATMENT OF THE CARRIER CONDITION

Since local applications have proved unreliable in the treatment of the carrier state, it seems to us that operative interference is the only solution of the problem, especially in those cases in which the tonsils can definitely be shown to be the focus of infection. In 77.2 per cent. of carriers, the bacilli were harbored in the tonsils. The majority of the remainder showed the presence of *B. diphtheriae* in the nose.

The tonsils should be removed in every case in which it can be positively demonstrated that they are harboring the organism. The contraindications for tonsillectomy in carriers are those that apply under other circumstances.

The majority of patients with clinical diphtheria remain in the hospital for a period of approximately four weeks before they are returned to their commands. Since, in the average case, the bacilli have disappeared by the end of the third week, this may be taken arbitrarily as the beginning of the carrier stage. Consequently, it is safe to remove the tonsils at this time, provided there are no contraindications.

The reaction in carriers, following operation, does not differ from that found in noncarriers. Occasionally it may be severe enough to arouse suspicion that clinical diphtheria is present. However, unless there has been operative traumatism to the surrounding structures, the limitation of the postoperative exudate to the tonsillar fossae—in contrast to the angry red, edematous throat of diphtheria, in association with the marked prostration—suffices to differentiate the two conditions.

Patients on whom operations were performed had been positive for a period varying from one week to several months. As nearly as could be determined, the proportion of primary to secondary carriers was as 2:1. Of the 294 carriers operated on, 20 per cent. yielded a positive culture from the nose and 57 per cent. from the throat, immediately before operation. Subsequent to operation the following results were obtained:

Ninety-four, or 32 per cent., had no positive returns.

One hundred and thirty-six, or 46.4 per cent., were negative by the end of the first week.

Thirty-eight, or 12.9 per cent., were negative by the end of the second week.

Eleven, or 3.7 per cent., were negative by the end of the third week.

Fourteen, or 4.7 per cent., were negative by the end of from four to eight weeks.

One, or 0.3 per cent., was still positive at the end of four months despite all treatment.

In those cases found to be persistently positive, acute or chronic infections of one or more of the accessory sinuses, septal deformities with erosions, or infected adenoid tissues were present.

The time of clearing, as shown by the 91.3 per cent. who were negative by the end of the second week, corresponds very closely to the time required for healing. As the postoperative exudate disappears and the wound heals and becomes smooth, the lodging places of the bacilli become obliterated. In one carrier with adenoid involvement the bacilli disappeared after the tissue was removed. In the persistent nasal carriers, clearance coincided with improvement in local conditions. On the cessation of the infection in the acute sinus cases, the carrier condition terminated.

In the chronic cases, drainage and constant attention to cleanliness helped, but only after a considerable time. Patients with atrophic rhinitis presented the greatest difficulty as, even after the most continued and careful treatment, and the return of more than the required number of negatives, there was no assurance that the bacilli had finally disappeared. The advisability of operating on these patients was considered, but the extensive involvement of the nose and accessory sinuses, with the resulting marked disturbances of function and nutrition, all advised against this. In addition, there was no assurance that crusts would not continue to form and thus serve to maintain the original condition. The question naturally arises as to what should be done with this class of patients. Chronic infection of the accessory sinuses disqualifies for admission into the service. Nevertheless, there are many such cases in the Army at present. It may not be practicable to have the opinion of a specialist on each individual in the service, but, in our opinion, every one connected with a base hospital should have a thorough examination of the nose and throat. Remediable conditions should have early attention. Chronic nasal diseases that offer no hope of early improvement or cure may necessitate discharge from the Army.

The disposition of a chronic nasal carrier with virulent bacilli is a question that will require much consideration. It may be solved partly by employing these patients in diphtheria wards where there are cases of diphtheria in the hospital or camp. What should be done with them at other times is the point to be decided. At present the isolation camp is the only solution. It is impossible to state the length of time during which the carrier condition may persist. To illustrate, one case that occurred in civil practice may be cited. An infant became a carrier at the age of 2 months. The bacilli

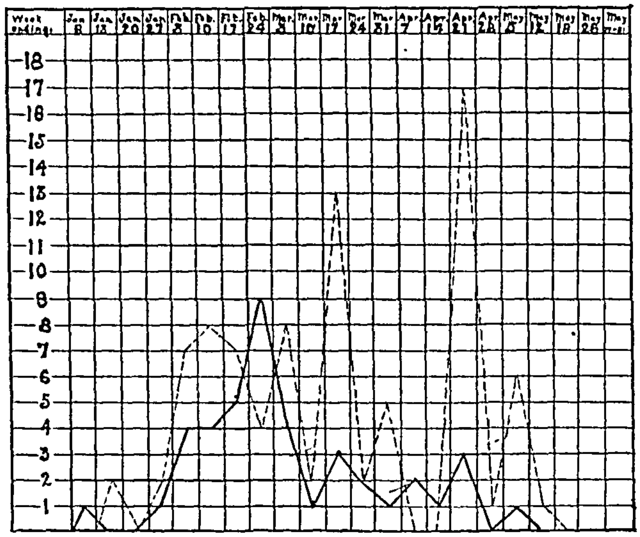

Chart 2.—Occurrence of diphtheria among the base hospital personnel: solid line, cases; broken line, carriers.

continued to be found for 251 days. Virulence tests made shortly before the condition cleared were positive.

CONTRIBUTORY FACTORS IN THE MAINTENANCE AND SPREAD OF THE EPIDEMIC

Measures undertaken for the control of any communicable disease must begin at the source of infection and continue until all danger of infecting others has passed. The following factors may counteract any or all of the defensive measures that have been instituted against an epidemic:

A. Delayed or mistaken diagnosis. This may be seen especially in cases of primary laryngeal diphtheria, which may remain undiagnosed for several days.

B. Ambulatory cases, usually of a mild or nasopharyngeal type. This was illustrated by a case in which a man was admitted to the hospital with the history of an indefinite nasal complaint of nineteen days' duration. A diagnosis of nasal diphtheria was made, which was confirmed by the laboratory. Yet, during the entire period of his illness, the patient had been doing full duty with his regiment.

C. Contiguity. The spread of disease by droplet infection is facilitated by close association in tents, barracks, wards, wash rooms, kitchens and general mess halls.

D. Fomites. Dishes, kitchen utensils, the use of the pipe, drinking cup, canteen, or musical instruments in common, mouth pieces of gas masks, unwashed bed linen, and laundry must all be taken into consideration as distributing agents in an epidemic.

E. Food supply. The milk supply should be investigated, especially when raw milk is being used.

F. Lack of appreciation of the seriousness of the carrier problem on the part of some of the members of the hospital organization, comparatively few of whom have previously had any experience with contagious diseases.

G. Improper methods of taking cultures. Cultures should be taken carefully and not by the "hit or miss" method so often employed. The most reliable results are obtained when cultures are taken from the tonsillar crypts and from the nose. Wound cultures should be made from the granulation tissue before the wound is dressed. Cultures from the nose and throat should be taken immediately before treatment.

H. False conclusions from defective material. Old or contaminated culture mediums may inhibit the growth of the diphtheria bacilli. The use for the Schick test of toxin which has deteriorated in potency may lead to erroneous conclusions as to the presence, in the body fluids, of sufficient antitoxin to protect the individual.

I. Release of patients from quarantine before negative cultures in sufficient number have been obtained, or before the necessary interval of time has elapsed.

J. Disregard of surgical principles in dressing wounds. Particular care should be taken that all gloves and instruments should be thoroughly sterilized for each case.

K. Lack of appreciation of the importance of carrying out quarantine regulations. The fact that the patient is needed by his organization or that there is a shortage of beds in the hospital should not be a sufficient cause for the premature release of a man from quarantine.

L. Undetected carriers. Individuals who have not been found positive by the laboratory, and patients with acute tonsillitis may be discovered to be carriers only when cultures are taken as a routine measure.

The causes for the maintenance or spread of an epidemic of diphtheria may be classified as avoidable and unavoidable. Inexperience, indifference, ignorance and carelessness are factors in the first group. Under unavoidable causes may be included legitimate errors in the diagnosis of atypical cases of diphtheria, clinically mild cases, carriers released after full compliance with the regulations, and, lastly, inadequate laboratory facilities.

CONTROL AND PREVENTION

The methods provided for the control of communicable diseases are so well known that a review would seem unnecessary. When the cases are few, the proposition may be simple; but when there are many to be dealt with and it is essential that company organization and the training of troops shall be maintained, the problem becomes more complex.

A. Centralization of control. For the attainment of efficiency and the accomplishment of results, centralized control is absolutely necessary, as division of responsibility tends toward weakness.

Clinical diphtheria is under the care of the hospital section of medicine. Suspect cases usually appear in the wards pertaining to head surgery. Nose and throat carriers may be found anywhere and are inherited by the latter service. Military or hospital exigencies may require frequent changes in attendants. Patients convalescent from diphtheria must be removed to make room for the acutely ill, and may be transferred to a convalescent camp. Since this may become overcrowded, the patients must in turn be moved to an isolation or quarantine camp. In the meantime, as a result of the conditions cited, cultures may have been overlooked or neglected.

In view of the fact that, in this series of cases, the laboratory passed on all cultures submitted and was therefore cognizant of the status, from a bacteriologic standpoint, of all cases of diphtheria, the following system was adopted for the control of the epidemic: Whenever a new positive culture was found, a record was made of the name, rank, organization, date of primary culture, and whether the patient was a case or carrier. The results of all subsequent cultures were added to this record. After three negative cultures had been obtained at three-day intervals, the chief of service was notified that the patient could be released from quarantine. In cases in which the positive returns persisted for a period of three weeks or longer, the matter was brought to the attention of the chief of the nose and throat service for further investigation.

B. Disposal of patients. Undoubted clinical cases of diphtheria were sent directly to the diphtheria wards by the receiving officer. All patients who were sent to the head surgery section were examined in the outpatient room before being admitted to the wards. Owing to the large number of acute inflammatory throat conditions admitted at this season, it was considered advisable to make cultures of every patient admitted to this service. Suspicious cases were isolated in private rooms. Separate wards were set aside for the reception of carriers. Known carriers from the camp or other wards were received there directly.

On account of the necessity of awaiting the laboratory report on cultures, the disposal of patients presented a problem. To meet this contingency, the following plan was evolved in conference with the commanding officer, the chief of the section of head surgery, and the chief of the laboratory: Five pyramidal tents, each having a capacity of four beds, were erected in the rear of the head surgery wards. All patients admitted to the service other than by transfer from other wards were examined, cultures were taken, and the patients were treated and then sent to the observation tents. On the return of the culture findings, patients with negative cultures were transferred to the clean wards, while those with positive cultures were sent to the carrier or diphtheria wards, according to the laboratory findings. Since the information furnished from the return of a single negative culture was found to be insufficient, the patients who had been sent to the clean wards were isolated in cubicles and further cultures were taken. If found negative on the second culture, they were allowed the freedom of the wards, but if found positive they were transferred to a carrier ward. All patients presenting symptoms suggestive of clinical diphtheria, even though the cultures were negative, were kept isolated in the observation tents or, if quite ill, in private rooms in wards until a definite diagnosis was made.

From the middle of February to the latter part of May, 680 patients were sent from the receiving office to the head surgery section for all causes. Of this number 127 were found to be either diphtheria carriers or cases: of these, fourteen patients were sent at once to the diphtheria wards; sixty-one patients were sent from the observation tents to the diphtheria wards at a varying number of hours after admission; thirty-two patients were sent to the carrier wards. Twenty patients who were negative on the first culture and who had been isolated in clean wards gave positive returns on the second culture. The extent of the epidemic may be readily appreciated when it is noted that 18.6 per cent. of all cases that passed through the head surgery section were either carriers or cases of diphtheria.

Routine cultures were taken, at five to seven day intervals, of the personnel and patients. The system of cubicle isolation and the establishment of carrier wards was soon extended to the other wards of the hospital.

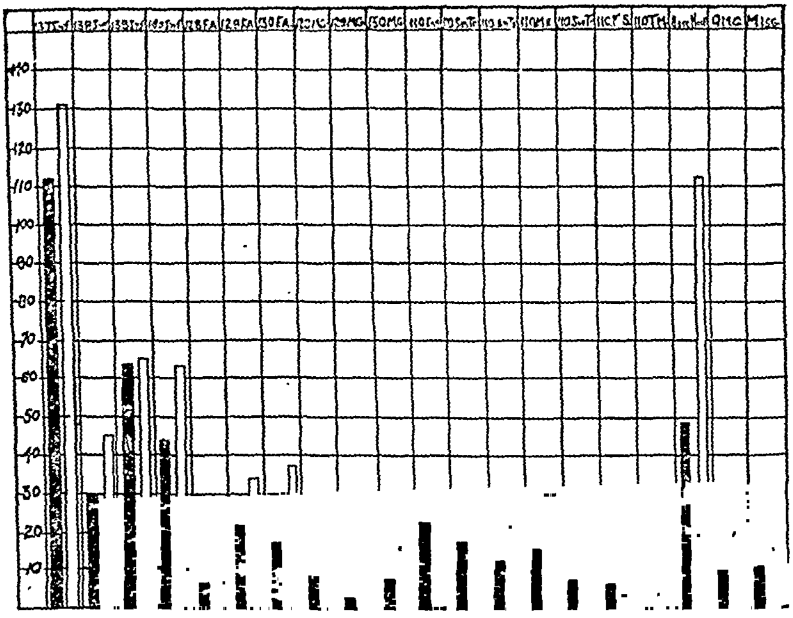

Chart 3.—Incidence by organizations of diphtheria and diphtheria carriers at Camp Doniphan, Oct. 1, 1917-June 1, 1918: solid blocks, cases; outline, carriers.

C. Masks. The protection afforded by masks may be real or imaginary. The simple gauze bandage is the poorest of all, since when worn by patients it may be found in any position between the chin and the forehead. The mouth and nose are rarely covered at the same time. The combined head and face (helmet) mask, if made of a material with a close mesh, is the most efficient and may be worn for some time with comparatively little discomfort. The thick gauze surgical mask which fits the mouth and nose closely is uncomfortable for continuous wear and, owing to the condensation of moisture on it, becomes unsightly. A mask that was found suitable for clinic work and ward visits was made of a copper wire frame covered with several layers of gauze held in place by small strips of adhesive plaster or by basting thread. It was similar in appearance to an anesthetic mask. The frame was bent to fit the nose and mouth closely. Tapes or paper clips that held a rubber band were attached to the sides of the mask, and by the slipping of these bands over the ears the mask was securely held in place. Its chief advantages consisted in the rapidity with which it could be adjusted or removed, and the absence of the discomfort that is found with all close-fitting masks. Conversation was not interfered with, which was also advantageous when clinical instruction was being given.

Despite regulations regarding the wearing of masks, it is very difficult to obtain complete observance with ambulatory patients and even with attendants. Sharp disciplinary measures are necessary to enforce compliance with the rules.

D. The Schick test. There is very little doubt that the Schick reaction, by determining the susceptibility of individuals to diphtheria, is of great value as an aid in controlling the spread of the disease. Of 1,035 Schick tests performed, eighty-eight (8.5 per cent.) were positive, while 947 (91.5 per cent.) were negative. Of the eighty-eight persons who yielded a positive reaction, fifteen developed diphtheria, while among those who showed a negative reaction only three contracted the disease. All carriers tested gave a negative Schick.

Faulty results will be obtained if the toxin used is not of the proper potency. This was demonstrated in the case of the three men who developed diphtheria after a negative Schick, for, on further investigation, it was found that this particular lot of toxin had deteriorated.

E. Toxin-antitoxin. That diphtheria antitoxin confers but a transient immunity is well known. This fact is further corroborated by our own observation of a group of men, a number of whom manifested a positive Schick reaction within from three to four weeks after the administration of immunizing doses of antitoxin.

Within the past four months fifty-eight Schick-positive individuals have been injected with three doses of a toxin-antitoxin mixture prepared by the New York Board of Health. As these men have been transferred from this station we have been unable to carry out further tests in order to ascertain whether or not they have developed an active immunity.

We appreciate the fact that the injection of toxin-antitoxin will not give rise to immunity until after three or four months and is, therefore, of but little value in an epidemic. We are aware, moreover, that the administration of immunizing doses of antitoxin to susceptible individuals during the epidemic, though they protect the patients for the time being, may, on the other hand, so sensitize them as to make further introduction of serum dangerous, since it may give rise to anaphylactic shock. Nevertheless, these measures are of decided value and should be employed.

F. Hospital rules for the control of the epidemic. To supplement or amplify the rules concerning communicable diseases as prescribed by the Office of the Surgeon-General, the following additional rules were promulgated as occasion demanded

1. Cultures will be taken from the nose and throat of all patients, ward attendants, and detachment personnel other than those employed in the wards, every seven days.

2. The receiving officer or officer of the day will have cultures taken from the nose and throat of all patients admitted to the hospital and will note that fact on the admission slip. If patients are too ill to have cultures taken in the receiving ward, cultures will be promptly taken by the ward officer.

3. It is directed that cultures from new cases entering the hospital be designated by writing across the request blank, "Field case," "For diagnosis," "Carrier" or "Release," as the case may be.

4. Masks will be worn by all members of the staff in all wards and by the patients in the diphtheria and carrier wards. The nose must be kept covered as well as the mouth.

5. Except in emergency, new personnel must show a negative culture and a negative Schick test before assignment to ward duty.

6. Nurses who are infected (patients and carriers) will be isolated in separate wards. Carriers will remain on duty but will be assigned to diphtheria wards only.

7. No contact will be permitted between patients from different wards. To insure this at meal times, all patients will be messed in their wards and no meals will be served in the mess hall.

8. Articles used in serving food (dishes, knives, forks, etc.) will be cleansed in the wards and then sent to the kitchen to be sterilized by boiling.

9. Visiting in carrier wards is forbidden.

10. Symptoms of sore throat in any member of the hospital organization will be immediately reported to the next higher authority. Cultures will be made at once and the individual isolated until the result is known.

11. Patients in clean wards who are found to be positive are to be transferred to carrier wards at once, and cultures are to be made of patients remaining in the clean wards.

12. Cultures of carriers are to be made daily until a negative is secured. Thereafter they are to be made every third day.

13. New patients in clean wards are to be isolated in cubicles and will not be allowed the freedom of the ward or latrine. A culture will be taken on the day of admission and on the following day.

14. Cases and carriers will not be released until notification of release from quarantine is received from the laboratory.

15. Cultures will be taken of patients received in the ward, by transfer from another ward, and these patients will be isolated until the results of the cultures are reported from the laboratory, unless cultures have been taken within three days prior to transfer.

16. All medical officers, nurses and enlisted attendants are to have a Schick test, and when this is found positive, toxin-antitoxin is to be administered for the purpose of immunization.

17. After discharge from the hospital, carriers and patients are to report once a week for culture of nose and throat for such a time as is deemed advisable.

EPIDEMIOLOGIC STUDY OF DIPHTHERIA

Chronologic Occurrence of Diphtheria.—That diphtheria is a disease of winter is well shown in Chart 1, since its incidence is much higher during the coldest months. Unfortunately, no differentiation was made between the cultures obtained from clinical cases and from carriers prior to January, 1918, but after that date all cultures submitted to the laboratory were designated as from clinical cases or otherwise. Almost perfect parallelism is seen to exist in this chart between the number of carriers and clinical cases. The great increase in the number of carriers over cases for the week ending May 5 was especially notable in the three organizations in which the greatest number of clinical cases for that week developed.

Occurrence of Diphtheria Among Hospital Personnel.—Examination of Chart 2, showing the occurrence of diphtheria and carriers among the hospital personnel, does not reveal the close parallelism that is seen to exist in Chart 1, since the number of carriers greatly exceeds the number of cases, except during the onset of the hospital epidemic, which occurred during the month of February. This is explained by the fact that the hospital attendants who were susceptible to diphtheria contracted the disease during the early part of the epidemic while, later, the constant exposure of those who were immune increased the proportion of carriers. It is of interest to note that a decided increase in the number of cases of diphtheria in the camp is followed, within a few days, by a similar increase in the number of cases among the hospital personnel. This may be noted by contrasting Charts 1 and 2 for the weeks ending February 17 and 24, March 31, and April 7, 14 and 21. This may naturally be attributed to the fact that the members of the base hospital received their infection from the patients admitted from the camp, and, since a period of incubation must elapse from the time of exposure to the time of the manifestation of the disease, the apex of the curve in Chart 2 would necessarily lag behind that of Chart 1.

Another source of infection, aside from the camp cases, was found within the hospital itself. On examination, the fact was revealed that approximately twenty carriers and patients were working in the detachment and hospital messes as cooks or cooks' police. Since the ambulatory patients from all clean wards congregated here for their meals, they were naturally subject to exposure to diphtheria. Corroborative evidence that this was a source of infection was adduced by the fact that the highest incidence of carriers and cases occurred in Hospital Barracks A and B, where most of the kitchen force was quartered.

Occurrence by Organizations.—On examination of Table 2 we find that organizations coming from rural communities have distinctly higher incidences of diphtheria than those coming from the cities. Thus a comparison of the four regiments of infantry, all having approximately the same strength and living under the same conditions, reveals the fact that the 137th and 139th infantries, coming from rural communities, have a higher percentage of cases and carriers than the 138th and 140th, coming from St. Louis and Kansas City, respectively. The same distinct difference may be seen to exist among the regiments of artillery, which were of like strength and lived adjacent to each other under similar conditions.

An apparent discrepancy in this statement may be found in the percentage of carriers and cases occurring among the base hospital personnel, which had a strength of approximately 500. This fact may be attributed, as has been mentioned in the discussion of Charts 1 and 2, to their continual exposure to the disease.

It is of more than passing interest to note that, in the study of empyema made during the past winter, those organizations that exhibited a high morbidity for empyema showed, in this survey, a high incidence of diphtheria. From these facts one must conclude that, as has already been shown by others, a man from a rural community is not as great an asset to his organization in the early part of his military career as is an urban individual.

CONCLUSIONS

1. A single negative culture is only of relative value, as is shown by the fact that preoperative cultures, taken from tonsils that later proved positive for diphtheria, were negative in 22.8 per cent. of the cases.
2. The importance of nasal cultures is shown by the fact that in routine cultures taken from carriers, 26 per cent. were positive from the nose.
3. Cultures from chronic carriers should be tested for virulence.
4. The carrier state is maintained by some underlying pathologic condition of the affected tissues.
5. In the great majority of cases the carriers harbor the bacilli in the tonsils; a few carry the germs in the nose only; a small group maintains the infection in both nose and tonsils.
6. Conclusions based on the results of local treatment should be founded on careful and prolonged bacteriologic study. Cultures should be taken immediately before treatment, or, if local treatment is being administered, this should be suspended for a number of days before cultures are taken. The results of local treatment are problematical, since the organisms are situated deeply in the tissues.
7. In persistent carriers in whom the focus of infection is the tonsil, enucleation offers the only certain procedure for terminating the carrier state.
8. The most persistent nasal carriers are those in whom chronic inflammatory or atrophic processes are found. It is almost impossible, in view of the varying culture returns, to state when the condition has finally cleared.
9. Centralization of authority is necessary for the control of an epidemic of diphtheria and diphtheria carriers in camp. Release of patients from quarantine should be under the supervision of the laboratory.
10. During an epidemic, patients should not be admitted to a clean ward unless they have had at least two successive negative cultures from the nose and throat.
11. Improperly constructed and improperly worn masks give a sense of false security.
12. The hospital personnel should be given a Schick test, and those giving a positive reaction should be immunized with toxin-antitoxin mixture.
13. Toxin for the Schick test should be prepared fresh, and no diluted toxin should be used after twenty-four hours. The undiluted toxin should be kept in the dark and in a refrigerator.
14. Intermittent chronic carriers should be employed as attendants in diphtheria wards or in quarantine camps. They should be separated from the hospital personnel and from their organizations.
15. Diphtheria patients may be discharged from the hospital after they have had at least three negative cultures at three-day intervals. Chronic carriers should not be discharged until cultures taken over a long period of time prove consistently negative.

TABLE 2.—OCCURRENCE OF DIPHTHERIA BY ORGANIZATIONS

Organization	Source	Carriers Per Cent.	Cases Per Cent.
137th Infantry	Rural	19.1	24.2
138th Infantry	Urban	6.7	6.6
139th Infantry	Rural	9.7	13.9
140th Infantry	Rural and urban	9.2	9.3
1 [illegible]	[illegible]	1.3	1.8
1 [illegible]	[illegible]	5.1	4.6
1 [illegible]	[illegible]	5.3	3.9
1 [illegible]	[illegible]	2.7	1.8
1 [illegible]	[illegible]	1.3	0.4
130th Machine Gun Battalion	Rural	2.3	1.7
110th Engineers	Rural and urban	3.0	4.9
110th Sanitary Train	Rural	3.0	3.6

110th Trench Mortar Battalion	Rural	0.4	0.0
Base Hospital	Rural and urban	16.7	10.6
Quartermaster	Rural and urban	3.2	2.1
Miscellaneous	Rural and urban	2.3	2.2

We take this opportunity of expressing our appreciation for the cooperation accorded us during this study to the following members of the staff of the base hospital: Major A. C. Magruder, Capts. W. B. Post, E. E. Hopkins, A. W. Cox, H. E. Blanchard, R. Appleberry and A. E. Edgerton, Lieut. F. H. Thorne, Miss Marjorie Bates, Miss Dorothy Loomis, and Pvt., First Class, Stephens Moore.

THE PROTECTIVE QUALITIES OF THE GAUZE FACE MASK

EXPERIMENTAL STUDIES

DAVID A. HALLER, M.D. (Pocahontas, Va.)
Major, M. R. C., U. S. Army
AND
RAYMOND C. COLWELL
First Lieutenant, S. C., N. A.
CAMP GRANT, ROCKFORD, ILL.

The use of the face mask by surgeons and their assistants to protect clean operative fields which they otherwise would spray with their own mouth organisms at every cough or sneeze is an old and well established procedure. The utilization of the face mask to protect the wearer from droplet infection in the presence of those ill with acute infectious diseases is likewise now a well established custom owing in large part to the careful studies at the Durand Hospital in Chicago. Weaver[1] has shown its efficacy when used in this institution in protecting attendants on infectious disease cases both from contracting these diseases and from becoming carriers of them. Capps[2] has published statistics tending to confirm the work of Weaver and has proposed a new adaptation for the face mask, the essential idea being to use this mask to protect patients from cross-infection in the ambulances, and in the admission rooms and wards of the hospital. The clinical results of this adaptation of the face mask were described by Capps[3] recently.

The work described in this paper was carried out for several reasons. The masks used at this hospital have come from several different sources. Masks found in use in the various wards *on the same day* showed extreme variation in the number of layers of gauze. Some were made with only three layers, and were obviously too thin. Others were made with eight layers, and these were quite hard to breathe through; also they were very warm and uncomfortable. The gauze of which the masks were made varied in quality, some being as fine as twenty-eight strands to the warp and twenty-four to the woof per inch. Other specimens showed twenty strands to the warp and fourteen to the woof per inch. The masks varied in size. Some we believed to be too small. A great difference was noted in the same mask before and after being washed. In addition to this variation in the masks, we judged that there was some difference between the protection afforded the uninfected individual by a mask when placed over the mouth and nose of the one infected and when an identical mask was placed over the mouth and nose of the uninfected, for the reason that in the latter situation the mask is at a greater distance from the source of the organisms, and they are not propelled against the mask with the force that they are when it is directly subjected to currents of air expelled from the mouth carrying numerous droplets of mucus and saliva, each one of which probably carries many organisms.

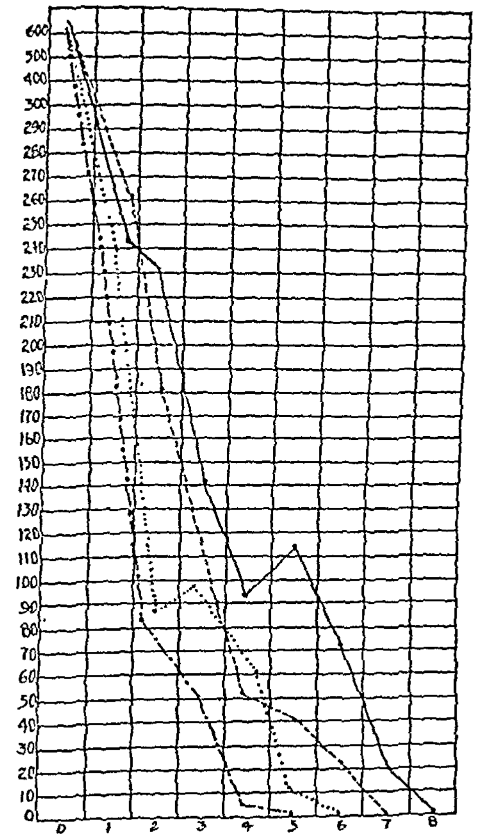
[3] Capps, J. A.: Measures for the Prevention and Control of Respiratory Infections in Military Camps, The Journal A. M. A., Aug. 10, 1918, p. 448.

One of us was found to be a badly infected carrier of typical pneumococci (Type IV) which could be distinguished on human blood agar plates from air-borne organisms of the room which were deposited on plates of the same mediums exposed at the same time in the same room. It was determined to have this individual cough directly at a Petri dish containing this medium, first without a mask and later with masks over the face, each succeeding mask being thicker by one layer than the preceding one. Masks tested varied in thickness from one to eight layers. The gauze used was Bauer and Black's or the equivalent of their specimens called, (1) B and B (32 by 26); (2) L and L (28 by 24); (3) Lakeside (24 by 20); (4) Dearborn (20 by 14).



Experiment with gauze over face: line of dots and dashes, B and B (32 by 26); dotted line, L and L (28 by 24); broken line, Lakeside (24 by 20); solid line, Dearborn (20 by 14).

The coughing was kept as nearly constant as possible, both in force and in the number of coughs. It was soon found that the first few coughs were usually rather unproductive and that it was necessary to have the individual cough several minutes before the coughs became roughly equal in productiveness. The Petri dishes were in every case at a distance of from 12 to 14 inches from the face. The gauze was unwashed and was sterilized in the steam autoclave at 15 pounds pressure for thirty-nine minutes and then allowed to dry before being used. A chart of the protocol of an experiment is given herewith. It will be noticed that if one takes the sum of the strands counted in the warp and in the woof in the case of each quality of gauze—B and B, 32 and 26, total 58; L and L, 28 and 24, total 52; Lakeside, 24 and 20, total 44; Dearborn, 20 and 14, total 34—and multiplies in each case by the number of layers of gauze necessary in each case to protect fully the exposed plate, these figures quite closely correspond: $5 \times 58 = 290$; $6 \times 52 = 312$; $7 \times 44 = 308$; $9 \times 34 = 306$.

The total number of colonies coughed through various layers of gauze cannot be compared directly with the total number of colonies coughed through one of the same series of masks resterilized and used at some other time, for the contamination of the mouth is not at all the same at different times. A complete series of masks must be run through at one sitting. This is done on several different occasions and the results for each mask averaged. The results with two or more patients can be compared only by taking the number of colonies on the respective control plates as a total and expressing all other counts in percentages of this total. The percentages can then be directly compared. The only constant feature in regard to the various masks seems to be the thickness at which absolute protection of the place is reached. This can be tested with very little trouble and without going through the entire series of masks. The conclusion reached is that the amount of gauze placed in superimposed layers necessary to give fully complete protection when the mask is worn over the face of the one infected lies very close to the equivalent of 300 strands of cotton fiber to the square inch.

In several instances the experiment was conducted as described, and in addition after each mask had been worn from five to fifteen minutes another Petri dish was then exposed and coughed at in the same manner. The object was to see whether the filtration was as efficient after the mask had been worn for some time as it was when first put on. The workers were biased in their belief that the mask would not be sufficient, and quite a large number of parallel and control experiments were necessary to remove this bias. It was, however, conclusively shown that no more organisms penetrate the mask after it has been worn for thirty minutes than when it is first applied to the face, provided, of course, all other factors remain constant. The mask if dried and reversed will become not a filter but a disseminator of organisms. Experiments to determine the effect of drying used masks which are then reapplied to the face have been so at variance with each other as to be quite inconclusive. It is our opinion, however, that this drying process is rendered practically harmless when the mask is reapplied without reversal after the patient has breathed through the mask several times and the expired air has been allowed to moisten it again. It seems that the practice as followed here of marking the face side of the mask by a small strand of black thread is a very good one and should be followed out in all masks.

Our second series of experiments was directed toward a determination of how many superimposed layers of gauze are necessary to protect when applied over the face of the uninfected, rather than over the mouth of the infected. To represent the recipient, a Petri dish was masked and coughed at from a distance of from 12 to 14 inches with no mask over the face of the subject. One feature entirely neglected in this experiment which is present in the actual clinical test of the mask is the inspiratory suction through the mask. The same series of masks were used although only one quality of gauze was completely worked out. This was the Lakeside (24 by 20). Five layers were necessary to protect the plate completely, which amount represents 220 strands of cotton fiber to the square inch.

A third series of tests were made with duplicate masks; one was placed over the face and one over the exposed plate, each succeeding mask being increased in thickness by one layer of gauze. The series embraces all thicknesses from one to eight. The gauze used for the series was Lakeside (24 by 20). The figures obtained tend to show that cotton fibers in superimposed layers of gauze to the extent of 350 to the square inch equally divided between the infected and uninfected will prevent droplet infection. This result may be interpreted as inconsistent with the figures of the protocol given. This apparent inconsistency is, we believe, quite within the limit of error of the methods used. It can be shown that the mask over the face of the infected is of value in the prevention of the uninfected when used in addition to the mask over the plate which represents the uninfected.

Experiments made with washed gauze demonstrated the following facts: The better qualities of gauze B and B (32 by 26), L and L (28 by 24) and Lakeside (24 by 20) become more efficient through shrinkage of the fiber, and if too thick at the outset become almost unbearable after repeated washing. Here also there is some question whether or not most of the respiratory exchange takes place about the edges of the mask, rather than through it. With the very poor quality of gauze, Dearborn (20 by 14), there is a decided tendency for the gauze to pull apart and leave very large gaps in the individual layers. We are of the opinion that this gauze should never be used for this purpose.

Work with the reknit gauze has demonstrated that it is almost impossible, because of its remarkable stretching, to estimate its efficiency. Even under ordinary conditions it does not remain the same for more than a few minutes at a time. We hesitate to recommend its use, as we have seen a thick mask so stretched out and thinned after an hour's wear that it was quite obviously useless.

A small amount of work was done with Turkish toweling. Preliminary experiments tend to show that one layer of this material makes a highly efficient droplet filter, and it is comfortable to wear. The question of expense, and also the question of the effect of wear on this material, are to be considered.

SUGGESTIONS FOR MASKS

1. It is our belief that gauze of the quality of Lakeside (24 by 20) or L and L (28 by 24) should be used in four layers, B and B (32 by 26) in three layers, provided all persons are masked. In case only the infected are masked, Lakeside (24 by 20) should be seven layers thick, L and L (26 by 24) six layers, and B and B (32 by 26) five layers. If the masks of this thickness are used, the ambulances and receiving offices and particularly the clothing of uninfected patients would probably not become infected.
2. Masks should be 8 inches in length with the edges turned in and stitched. They should be 5 inches in width.
3. Two braids should be used, each 1 yard long and sewed along the upper and lower borders of the mask so as to leave a free end 14 inches long at each side.
4. The masks should be marked on the face side by a black thread tied in the gauze.

THE ARMY SHOE AND MILD FOOT DISABILITIES

J. TORRANCE RUGH, M.D.
Lieutenant-Colonel, M. C., U. S. Army.
PHILADELPHIA

Extensive foot inspections were made of the soldiers who were trained during the latter half of 1917 and early part of 1918. These inspections were first made when the men were inducted into service and while the feet still showed the abnormal conditions that were present in civil life, and again before they were sent overseas. Comparison of the results of the two examinations disclosed that marked changes had occurred, and the experience of civil orthopedic practice is verified by these observations. These changes have been almost uniformly favorable to better function of the feet, and when unfavorable results have occurred, the reason has been readily traced.

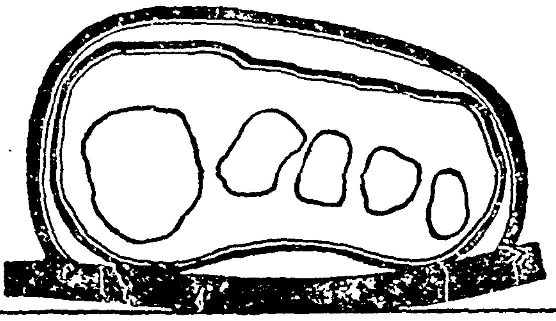
In endeavoring to account for the marked changes observed, there are two factors that stand out as most potent. First is the Army shoe and second is the increased personal care and interest in foot health on the part of the officers and men from the instruction by the orthopedic surgeons.

Extensive observation (covering several hundred thousasd cases) shows that 98 per cent. of the recruits can be fitted with the Army shoe. This fact alone is the strongest possible recommendation for its use, but an additional fact still more strongly recommends it. This is the beneficial influence of the shoe on the foot of the wearer. When a shoe is properly fitted at the beginning of service, there should be about two-thirds inch between the end of the longest toe and the end of the shoe. After from four to six months of training there should be at least half an inch. The heel should be held fairly snug in the shoe, the vamp should fit smoothly over the forefoot, and the ball of the foot should rest in its seat near the posterior turn of the sole. In fitting shoes, it must always be remembered that a shoe will enlarge sidewise but never lengthwise. Also, that repairing tends to shorten a shoe, and rebuilding actually does shorten it.

Short shoes cause more foot troubles than narrow ones; hence the great need of the two-thirds inch room in the length of the shoe to accommodate the lengthening of the foot in the first four or five months of training. This length and breadth of shoe permits a degree of function hitherto unknown to the foot. There is greater freedom of toe action, which affects both muscles and joints. This is followed directly by lengthening of ligaments, increase in size of muscles and alteration of relations of all the anatomic elements of the foot. These factors contribute directly to an increase in the size of the part. I have repeatedly seen cases in which the original size of the shoe had been strongly objected to as being entirely too large, but after a few months of intensive training and perhaps using extra or thicker socks, the fit was entirely satisfactory by reason of the development of the foot.

With the greater freedom of action in the larger shoe, there occurs absence of pressure on toe-joints, and corns disappear. There is freedom from pressure on nails, and "ingrowing" gradually ceases, especially if a little aid is given by proper cutting and attention. Toes that have been crowded together have sufficient room for normal function, and under the constant muscle pull and better distribution of weight, both of which forces are almost constantly active in the soldier's foot for from twelve to fourteen hours a day, they gradually assume a normal relation. In many instances, a moderate degree of overlapping has gradually lessened to a very nearly normal position. Similar results obtain in various other conditions in which secondary pathologic changes have not produced a degree of permanence that will yield only to surgery. These superficial conditions are always of mechanical origin, and almost universally from improper foot coverings, not from faulty function primarily. When, therefore, these mechanical conditions are remedied or removed, the effects disappear and the part gradually develops into as nearly normal a state as is compatible with existing pathologic changes or conditions.

As the result of greater freedom of action, the intrinsic muscles of the foot, which have long been inactive and atrophied, gradually resume again their function. This chiefly concerns the maintenance of the transverse and longitudinal arches. With increase in activity, there is also increase in size. The foot develops power and endurance. The fibrous attachments strengthen to meet the greater strain. Circulation improves by reason of the greater functional activity and the lessening of constriction. This promotes nutrition and a beneficial circle is established to replace the former vicious one. Greater elasticity and increased range of motion in the various joints of the foot allow a greater variation in its length from changing function and strain. The tonicity of the large leg muscles also improves and the support essential to weight-bearing and progression is readily developed. This in turn gives a better position to the foot so far as concerns the carrying of the body weight, and the onset of static disability is prevented.



Foot resting on the two sides of a concave inner sole, without support to the transverse arch.

One other very striking result from the wearing of the properly fitted shoe is in troubles with the transverse or metatarsal arch. Foot inspection shows a large number of men with callosities under the metatarsal heads (ball of the foot). This means a loss of the transverse arch, and may be associated with metatarsalgia (Morton's foot) or with painful callous areas or both.

The preservation of the transverse arch depends mostly on the strength of the intrinsic foot muscles and the vicious circle following the wearing of improper shoes is readily succeeded by sagging and loss of this arch. Furthermore, in the manufacture of a shoe, the inner sole is likely to be concave instead of convex. This is due to the fact that the sole of the last is convex; hence, as the leather is fitted over it, the result is a concave surface inside. The foot then rests on the two sides of this and has no support in the center, as in the accompanying illustration. If now the muscles that furnish support are weak and atrophied, severe use will almost surely result in loss of the foot arch (transverse) before sufficient power can be restored to them.

From the foregoing will be readily seen the great need of proper fitting of the shoes to maintain the best health of the feet. The regulation army shoe has all the essential qualities for foot health and is proving its worth to the soldier. The educational phase of the problem on the soldier is an equally great one, and its influence will persist for a long period after the war ends. The soldier will be a center for education in proper foot wear by reason of his comfort in shoes that are long enough and which conform to the shape of the foot.

FACE MASKS IN INFECTIONS OF THE RESPIRATORY TRACT*

BREWSTER C. DOUST, M.D. (Syracuse, N. Y.)
Captain, M. C., U. S. Army

AND

ARTHUR BATES LYON, M.D. (Boston)
Lieutenant, M. C., U. S. Army

NEW YORK

The use of face masks by those whose duties necessitate their coming in contact with cases of respiratory infection has now become general. The object of such masks is twofold: first, to protect the wearer against infectious material from the respiratory passages of the patient, and second, to protect the patient from such material as the attendant may himself carry in his mouth and nose. The types of masks worn, however, have been variable, and the efficiency of many of these types as barriers to the transmission of bacteria is certainly open to question. We have therefore undertaken experiments with some of the commoner types of masks in order to prove their efficiency or nonefficiency in preventing the dissemination of infectious material from the mouth during the acts of speaking or coughing.

Our first object was to determine, by means of agar plates exposed at different distances from an observer, how far infectious material might be projected from the mouth during speaking or coughing.

Our second object was to determine to what degree the wearing of a mask modified the projection of such material during the same acts.

METHODS AND TECHNIC

B. prodigiosus was selected as a suitable organism to introduce into the mouth for these experiments, because of its innocuous character, and because its pigment formation makes its recognition easy on agar plates.

For our experiments two small rooms were selected which were used for no other purpose during this time. Each of these rooms contained a metal topped table and a chair. The arrangement of the furniture is shown in Figure 1. When the observer was seated in the chair, the table top was just below his ensiform. Agar plates exposed on the surface of the tables before the beginning of the experiments showed no *B. prodigiosus* present in the circulating air and dust.

---

*From the Hospital of the Rockefeller Institute for Medical Research.

Experiment 1.—*To determine the limits of projection of B. prodigiosus from the mouth during ordinary speech, loud speech and coughing.*—The observer first thoroughly rinsed his mouth and gargled his throat with a suspension of *B. prodigiosus* in 0.85 per cent. sodium chlorid solution, the viability of which was proved by subcultures at suitable intervals. The observer then entered the room and seated himself in the chair, facing down the length of the table. In line with the observer's mouth, agar plates were exposed from 1 to 6 feet distant, except in some of the coughing experiments, when plates were exposed up to a distance of 10 feet.

The observer then proceeded: (1) to talk in an ordinary conversational tone for five minutes; or (2) to talk in a loud tone for five minutes; or (3) to cough as much as possible for five minutes. In one instance ordinary conversational speech was maintained for a period of thirty minutes. At the conclusion of his speaking or coughing, the observer left the room. In order to allow the droplets in the air, if present, to settle on the surface of the plates, the plates remained exposed an additional ten minutes after the period of speaking or coughing. The colonies occurring on the plates were counted and recorded after seventy-two hours' incubation at room temperature.

Agar plates were exposed for one hour in the rooms between different stages of this experiment. By this means we found that an eight hour interval between the periods of talking or coughing was sufficient to insure the absence of *B. prodigiosus* in the circulating air.

The results of the projection of *B. prodigiosus* from the uncovered mouth during ordinary conversational speech, loud speech, and coughing, are shown in Table 1. The experiments were paralleled by two observers working in separate rooms.

* Number of colonies of B. prodigiosus on each plate in boldface figures; dash indicates plates not exposed.

Summary of Table 1

1. *Ordinary Conversational Speech for Five Minutes.*—In three out of four trials, *B. prodigiosus* was recovered in small numbers on plates 1 or 2 feet distant, but no farther.

2. *Ordinary Conversational Speech for Thirty Minutes.*—One trial. *B. prodigiosus* was recovered only on the 1 foot plate in slightly larger numbers than in any of the preceding experiments.

3. *Loud Speech for Five Minutes.*—In three out of four trials, *B. prodigiosus* was recovered in moderate numbers on plates from 1 to 4 feet distant.

4. *Coughing for Five Minutes.*—In all of four trials, *B. prodigiosus* was recovered, usually in large numbers, on plates up to 6 feet distant.

In two trials in which plates were exposed up to 10 feet, *B. prodigiosus* was once recovered up to 7 feet, and once up to 10 feet.

MASKS

For the subsequent experiments, masks were used. The masks employed by us were of uniform construction, but differed in the nature of the material used and in thickness.

Three sorts of material were employed: (1) coarse gauze; (2) medium gauze, and (3) buttercloth (Fig. 2). From each sort masks were made of from two to ten layers in thickness.

Each mask was about 6 by 8 inches, hemmed on the edges, and made with four plaits on each lateral edge. The mask was equipped with tapes on the four corners by which to tie it behind the head (Fig. 3). When extended to the full width by a fanlike extension of the plaits, the mask presented sufficient surface to cover nose and mouth, and to come below the chin (Fig. 4).

Experiment 2.—*To determine the effect of a coarse gauze mask on the projection of B. prodigiosus from the mouth during ordinary speech, loud speech, and coughing.*—The methods and technic of this experiment were the same as in Experiment 1, except that during talking or coughing a coarse gauze mask was worn. Each of the experiments of speaking in an ordinary tone, speaking in a loud tone, and coughing, was done with each mask of from two to ten thicknesses of gauze. The results of these experiments are shown in Table 2.

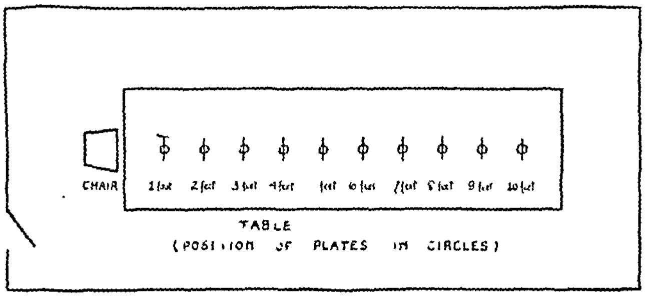

Fig. 1.—Arrangement of furniture and plates for tests.

Summary of Table 2

Coarse gauze masks worn from two to ten layers thick.

1. *Ordinary Conversational Speech for Five Minutes.*—One trial with each mask. *B. prodigiosus* was recovered five times, always in small numbers, on plates at variable distances. Three times organisms were found at 2 to 3 feet and twice at 6 feet. The latter possibly represents an error, as even without masks we never recovered organisms at this distance during ordinary

speech. The error, if present, is insignificant, since the remaining data are conclusive.

2. *Loud Speech for Five Minutes.*—With each mask, one trial. *B. prodigiosus* was recovered on plates from 1 to 4 feet distant with every mask up to eight thicknesses—in fairly large numbers with those up to four thicknesses, and in small numbers with those of from five to eight thicknesses.

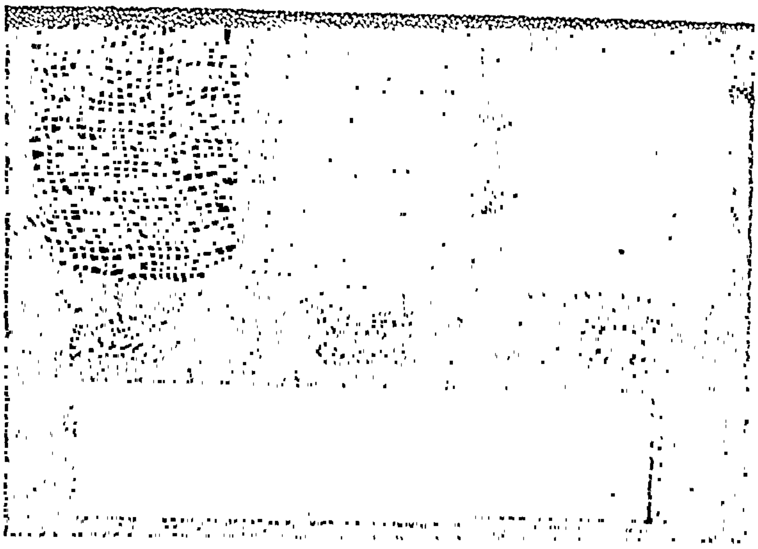

Fig. 2.—Material employed for masks.

3. *Coughing for Five Minutes.*—With each mask, one trial. *B. prodigiosus* was recovered in every instance. It was recovered in large numbers with masks of six thicknesses or less, up to 6 feet. With masks of greater thickness it was recovered in larger or smaller numbers at a distance of 2 or 3 feet.

Experiment 3.—*To determine the effect of a medium gauze mask in the projection of B. prodigiosus from the mouth during ordinary speech, loud speech, and coughing.*—The methods and technic of this experiment were exactly the same as in the preceding, except that the masks used were of a closer meshed gauze. The experiments of talking in an ordinary tone, talking in a loud tone, and coughing were repeated with each mask of from two to five layers in thickness.

Since the masks of from three to five layers proved to be effective as a barrier to organisms during ordinary speech, this experiment was abandoned with the thicker masks. Only loud talking and coughing were attempted with the masks of from six to ten layers.

The results of this experiment are shown in Table 3.

Summary of Table 3

Medium gauze masks worn, from two to ten layers thick.

1. *Ordinary Conversational Speech for Five Minutes.*—With each mask of from two to five layers, one trial. *B. prodigiosus* was recovered in small numbers only on the 1 foot plate with two layer mask.

2. *Loud Speech for Five Minutes.*—With each mask of from two to ten layers, one trial. *B. prodigiosus* was recovered in five cases, never beyond 4 feet, usually in small numbers. The 1-foot plate with the two layer mask was heavily seeded.

3. *Coughing for Five Minutes.*—With each mask of from two to ten layers, one trial. In every instance *B. prodigiosus* was recovered in moderate numbers on plates from 2 to 6 feet distant.

Experiment 4.—*To determine the effect of a buttercloth mask on the projection of B. prodigiosus from the mouth during ordinary speech, loud speech and coughing.*—The methods and technic of this experiment were the same as used in the preceding, but the masks used were made of buttercloth. Ordinary speech, loud speech, and coughing were repeated with each mask of from two to ten layers in thickness.

The results of these experiments are shown in Table 4.

TABLE 4.—PROJECTION OF B. PRODIGIOSUS FROM THE MOUTH WHILE THE FACE IS COVERED WITH A MASK OF BUTTERCLOTH

Summary of Table 4.

Buttercloth masks worn, from two to ten layers thick.

1. *Ordinary Conversational Speech for Five Minutes.*—With each mask, one trial. *B. prodigiosus* not recovered.

2. *Loud Speech for Five Minutes.*—With each mask, one trial. *B. prodigiosus* not recovered.

3. *Coughing for Five Minutes.*—With each mask, one trial. *B. prodigiosus* recovered at 2 feet with the two layer mask only.

Repetition of the coughing experiments while two or three layer masks, both washed and unwashed, were worn, showed like results.

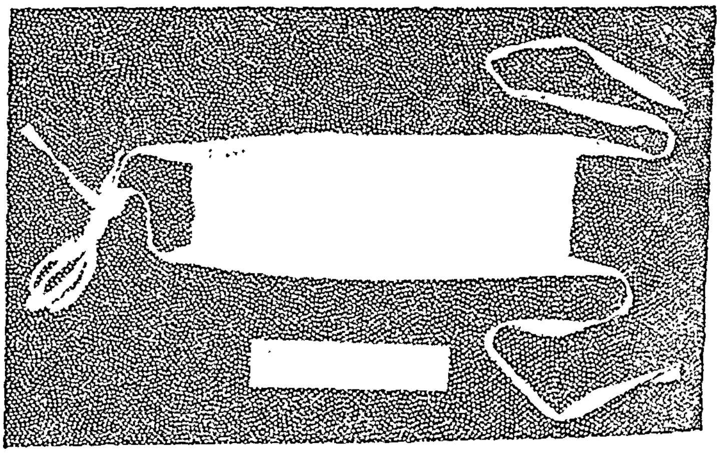

Fig. 3.—Mask, with tapes.

COMMENT

In 1899, Flügge and his followers,[1] working on the problem of tuberculosis infection, first advanced the theory of droplet infection. Briefly speaking, their experiments showed that if an observer retained in his mouth a suspension of *B. prodigiosus*, the organism could be recovered on agar plates a meter distant during the acts of speaking, sneezing or coughing. In general they believed that if a person were coughed at from a distance of less than a meter, he might be infected by means of the projected droplets.

---

[1] Flügge: Ztschr. f. Hyg., 1899, **30**, 107. Laschschenko: Ibid., p. 125. Heyman: Ibid., p. 139. Hillyer: Brit. Med. Jour., 1903, **1**, 595

From our own work, however, we judge that the infected zone has a considerably greater radius. Our data indicate that during ordinary or loud speech, droplets are rarely projected more than 4 feet, irrespective of the duration of the experiment. In talking for thirty minutes there was no greater projection of bacteria than in talking for five minutes, though during the longer time there may be a heavier seeding of a plate within the effective range. During coughing, however, the danger zone is immensely widened. We were surprised at the distance we could project the organisms during a hard spell of coughing. At first we exposed plates only to a distance of 6 feet. Subsequently we exposed plates up to a distance of 10 feet, on which we recovered *B. prodigiosus* in sufficient numbers to suggest the possibility of even greater projection. We found that the chances of recovering *B. prodigiosus* from the more distant plates were increased if the observer renewed the organisms in his mouth during the period of coughing. From our work it would seem that the danger zone about a coughing patient has at least a 10-foot radius.

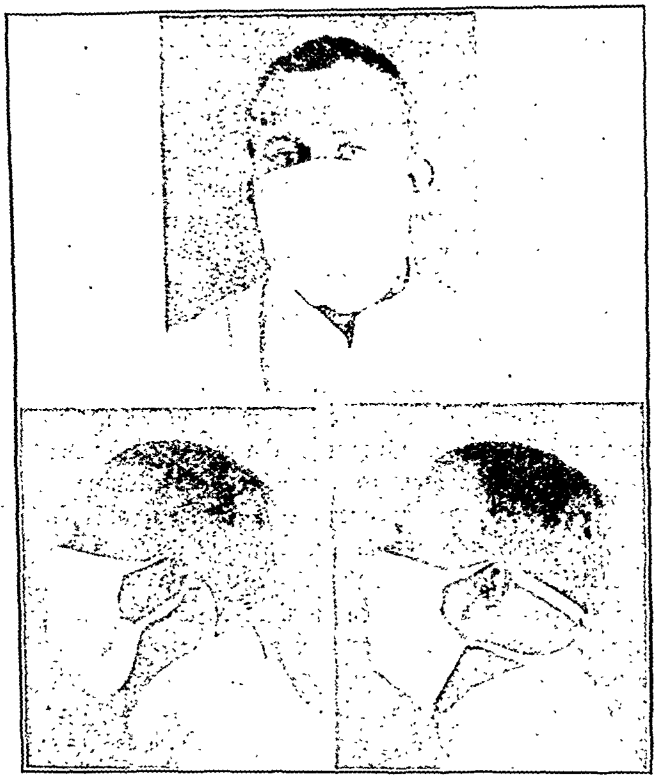

Fig. 4.—The mask as worn.

Our work has also convinced us of the futility of masks constructed from the coarser types of gauze, irrespective of thickness. We were constantly able to cough organisms through ten thicknesses of such material. A three layer buttercloth mask, however, appears to be effective in preventing the distribution of organisms from the mouth even during violent coughing. We have repeated experiments with this mask both before and after washing, with uniform results. Such a mask is not only effective, but easy to make and perfectly comfortable to wear.

These masks are also inexpensive. The quoted price per square yard of buttercloth is 14 cents. A square yard makes nine masks, each three layers in thickness. Each mask requires fifty-six inches of tape, costing about 2 cents. The cost per mask therefore is only between 3 and 4 cents, exclusive of labor. A mask may be repeatedly washed and used indefinitely. An indelible mark should be made on one side of the mask, and when the mask is put on, the same side should always be next to the face.

We have been using these masks in the Hospital of the Rockefeller Institute for physicians and nurses, and in some instances for patients; for example, during carriage to and from the roentgen-ray room, or when being moved about the corridors. They have also been used for ambulatory patients with head colds or other mild respiratory infections.

CONCLUSIONS

1. During ordinary or loud speech, infected material from the mouth is rarely projected to a distance of 4 feet, and usually less. A 4-foot danger zone exists about the patient under these conditions.
2. During coughing, infected material from the mouth may be projected at least 10 feet. The danger zone about a coughing patient has, then, a minimum radius of 10 feet.
3. Masks of coarse or medium gauze of from two to ten layers do not prevent the projection of infected material from the mouth during coughing. Such masks are worthless, therefore, in preventing the dissemination of respiratory infections.
4. A three layer buttercloth mask is efficient in preventing the projection of infectious material from the mouth during speaking or coughing. It is a suitable mask, therefore, to be worn in connection with respiratory diseases.

New and Nonofficial Remedies

The following additional articles have been accepted as conforming to the rules of the Council on Pharmacy and Chemistry of the American Medical Association for admission to New and Nonofficial Remedies. A copy of the rules on which the Council bases its action will be sent on application. W. A. Puckner, Secretary.

SOLARGENTUM-SQUIBB.—A compound of silver and gelatin, containing 19 to 23 per cent. of silver in colloidal form.

Actions and Uses.—See Silver Protein Compounds (New and Nonofficial Remedies, 1918, p. 361).

Dosage.—Solargentum-Squibb is used in solutions containing 1 to 25 per cent., or more. It is also used in the form of bougies or suppositories.

Manufactured by E. R. Squibb & Sons, New York. No U. S. patent or trademark.

Solargentum-Squibb is produced by the interaction of silver oxide and gelatin in the presence of an alkali. When combination has occurred, the solution is concentrated *in vacuo* and the product scaled.

Solargentum-Squibb occurs in the form of black, lustrous, odorless, non-hygroscopic scales. It is very soluble in distilled water; insoluble in oils and alcohol.

No precipitate is produced when sodium chloride solution is added to an aqueous solution of solargentum-Squibb. An aqueous solution of solargentum-Squibb does not precipitate albumin; it is decomposed with precipitation by addition of free acids; ferric chloride decolorizes the solution.

To about 1 Gm. of powdered solargentum-Squibb, accurately weighed in a porcelain crucible, add a mixture of 4.5 Gm. of lead oxide and 0.5 Gm. of powdered tartaric acid. Rotate and mix in a crucible. Heat continuously until thoroughly carbonized and then heat in a blast flame until the lead button formed is about half its original size. Allow the crucible to cool, then place it in a beaker and dissolve the lead button containing the silver in dilute nitric acid. Transfer liquid, with washings, into an Erlenmeyer flask and titrate the silver nitrate with tenth-normal potassium sulphocyanate volumetric solution, using ferric ammonium sulphate as an indicator. The silver content corresponds to not less than 19 per cent. and not more than 23 per cent. of metallic silver (each Cc. of tenth-normal potassium sulphocyanate volumetric solution is equivalent to 0.0107 Gm. silver).

SATURDAY, OCTOBER 12, 1918

QUARANTINE AND ISOLATION IN INFLUENZA

As indications of the attitude of civilian health officials with respect to the value and practicability of quarantine in influenza, it may be noted that the Illinois Department of Health has ordered that the patient must be quarantined until all clinical manifestations of the attack have subsided and the temperature has been normal for three successive days; that in New York City the patient is quarantined and, furthermore, so it is stated, the health department is prepared to compel patients "who may be so situated as to be a menace to the community to go into hospitals." In these and other places, influenza and pneumonia have been made reportable diseases.

The officials of the Navy at first glance seem to be of a different opinion in regard to quarantine in influenza, as indicated by the following extract from Bulletin 37,[1] of the Division of Sanitation of the Bureau of Medicine and Surgery, dated Aug. 9, 1918:

> *Control in the Navy.*—Quarantine and isolation are impracticable on account of the wide distribution of the organism [*B. influenzae*] in healthy persons and the number of unrecognizable cases.

This sounds like a decidedly reactionary statement, but it is possible that it refers to the units in which cases arise, or possibly to persons who have been in especially close contact with those that fall sick, because the remaining sentences of the paragraph read:

> Patients, however, should be put to bed at once, and bed isolation, prevention of droplet infection, and prompt disinfection of mess gear, handkerchiefs, etc., practiced as in measles. Where sick bays or wards are not available for isolation, the use of sheet screens between patients is to be recommended.

Whatever the real meaning of the sentence to the effect that quarantine and isolation are impracticable, the danger to life from influenza in this epidemic is so grave that it is imperative to secure for the individual patient the most complete isolation, whether in home or hospital, not only to prevent the spread of infection from the patient but also to prevent new and secondary infections from reaching the patient. This need to protect the sick is not emphasized in current advice and instructions to the public from the official and other sources. It appears, too, that in many if not most hospitals little or no attention is paid to the danger of cross-infections with virulent bacteria among their influenza patients. So far as we know, the actual situation in influenza seems to be this: THE PRECISE CAUSE OF THE PRIMARY ACUTE RESPIRATORY INFECTION IS NOT KNOWN—IT MAY BE THE INFLUENZA BACILLUS; AS YET DEFINITE PROOF IS WANTING—BUT THE MOMENTOUS PERIL SO FAR IS THE DEVELOPMENT OF PNEUMONIA, AND THIS APPEARS TO BE ASSOCIATED WITH AND IN ALL LIKELIHOOD CAUSED BY DIFFERENT BACTERIA, OF WHICH THE INFLUENZA BACILLUS, HEMOLYTIC STREPTOCOCCI, AND PNEUMOCOCCI ARE THE MOST IMPORTANT. We know that in experiments, streptococci and pneumococci may be raised enormously in virulence by successive animal passage, and there is good reason to believe that the virulence for man is increased by repeated transmission from patient to patient. The influenza bacillus may act in the same way, that is, a particular strain may acquire increasing virulence as it passes from the respiratory tract of patient after patient. It is to guard against dissemination by contact and droplet infection of strains with exalted virulence that individual isolation is demanded. The conditions in the present influenza outbreak are analogous to those in the cantonments with respect to streptococcus bronchopneumonia in measles, and are to be met in the same ways so far as possible. It is realized that at present the situation in many places is such that individual isolation and other measures to prevent cross-infection are out of the question; but the importance of the principle discussed must be recognized so that with time our methods of caring for respiratory infections may become more and more effective.

ADEQUATE SUPPLY OF PHYSICIANS MAKES LOWER EDUCATIONAL STANDARDS UNNECESSARY

According to the Census Bureau estimate for 1917, the population of the United States was 106,543,317, and according to the new American Medical Directory, the total number of physicians is 147,812. At the present time, therefore, there is one physician to every 720 people. In the various countries of Europe, just before the world war began, the proportion of physicians, according to the best available authorities, was from one to every 1,500 to one to every 2,500 people.[1] Numerically speaking, therefore, more than half of the physicians of the United States, or actually 76.783, might be withdrawn from civil practice before the proportion to the population would be as low as the highest proportion in any country of Europe, namely, one to every 1,500 of population. One physician to every 1,500 people could readily supply all the needs in thickly populated communities, but the more sparsely settled rural communities would doubtless need a larger proportion—say one to every 1,000. On this basis for the entire country, it would require one physician for about every 1,200 people. If properly distributed, this would be a reasonable proportion considering the improved roads and other means of accessibility by which a physician can now cover a much wider territory than heretofore. Based on the number of applications now going through for commissions in the Medical Department of the Army, there will be at least 35,000 physicians who have been commissioned or will have been offered commissions in the Army and the Navy by Nov. 1, 1918. As a maximum, however, not more than 40,000 physicians could possibly be needed by the government service unless the war should continue more than two or three years longer. This would still leave in civil practice one physician to every 988 population. The annual output from the medical schools in recent years has been approximately 3,000 physicians, more than covering the annual loss from deaths.

---

[1] Measures for the Prevention of the Introduction of Epidemic Influenza, Pub. Health Rep., 1918, **33**, 1540.

[1] We have not included in these calculations the thousands of osteopaths, chiropractors, naprapaths, physcultopaths, and other cult practitioners who, outside of the United States and Canada, are not to be found in other countries.

It is evident, therefore, that so far as the supply of physicians is concerned, there is clearly no danger of a shortage being produced by the present world war even if we should be called on to supply the needs of some of our allies. Consequently there is positively no basis for arguments favoring the reduction of educational standards. As a matter of fact, our medical colleges might all be closed for several years and the annual supply of physicians entirely cut off, and the number of physicians in the United States would still remain in a higher proportion to the population than in the most favored country of Europe. The only valid reason why medical schools should be kept going is that in recent years they have turned out physicians who are eminently better qualified than those of earlier years, and this one reason would be removed if educational standards should be lowered. It is only during the last eight or ten years that the majority of medical graduates each year have had the benefit of higher preliminary qualifications, of better equipped laboratories, of better hospital facilities, and of a training under larger numbers of full time, salaried, expert teachers. Our superabundance of physicians is mostly made up of those who did not have the benefit of these greatly improved conditions in medical schools, many of whom, however, be it said to their credit, through graduate courses and study, have kept up with the advances made in medical knowledge.

Those who are arguing for a reduction in standards on the plea that there is a need of physicians are either misinformed in regard to the facts or have certain special interests which they are striving to uphold. In the light of these facts it is urged that licensing boards generally enforce the present reasonable standard of two years of collegiate work as the minimal requirement of preliminary education. The argument that there is a dearth of physicians should not be looked on as an excuse for lowering educational standards in the interest of any pseudomedical cult. Let the present educational standards, which have been successfully established in recent years, be upheld so that the name of America, from the standpoint of medical education, may retain the high position educationally that it has recently attained among civilized nations.

IS EPIDEMIC POLIOMYELITIS PREVALENT IN ENGLAND AND FRANCE?

During the last six months there has been observed in England[1] and France[2] what has seemed an epidemic of a rather obscure origin. The various names applied to the condition—infective ophthalmoplegia, toxic ophthalmoplegia, acute infective ophthalmoplegia, acute encephalitis, epidemic lethargic encephalitis, botulism, Heine-Medin disease, etc.—show that considerable doubt prevails as to its nature. In England the largest number of cases have been recorded in London, but cases have been reported from many other parts of that country and of Wales.

According to Hall,[1] the main features of the cases so far observed are as follows: The patient, while in ordinary health, begins to be languid and drowsy, with or without other symptoms. In a few hours or days the weakness has increased and, indeed, may amount to complete prostration, so that he lies helpless in bed and can hardly move a muscle. Now the drowsiness becomes more marked and deepens into lethargy. Fever may be absent, or it may be present from the first, become severe, and persist. Cerebral excitement and delirium have been prominent features in some cases. In most cases, local symptoms pointing to lesions in the bulbopontile area are present at some time or other. Of these, ptosis, ophthalmoplegias of varying extent, nystagmus, facial palsy of lower neuron type, unilateral or bilateral, speech affections and dysphagia have occurred in different combinations in different cases. Muscular tremors of a curious kind have been noted in some. In some cases the general muscular asthenia has been more marked on one side of the body than on the other—either arm alone or arm and leg.

[2] Netter: Epidemic Lethargic Encephalitis, Bull. de l'Acad. de méd., 1918, **79**, 337.

Lumbar puncture has been negative bacteriologically and otherwise. Persons of all ages have been affected, but by far the majority of all cases have occurred in persons over 20 years of age. Sex and occupation seem to play no part, and in only one instance were there two cases in one family.

There has been observed congestion of the meninges and small hemorrhages in the brain substance, sometimes so large that the spinal fluid is bloody. There is cellular infiltration around the vessels and especially those in the bulbar and basal nuclei. Other parts of the brain may be involved.

In England the mortality has approached 20 per cent.; in France it was over 50 per cent., but the recovery seems to be complete in those that survived. The disease may last only a few days or it may persist for weeks or two or three months or more, the patient finally recovering when a fatal termination seemed inevitable, the sacrum, buttocks, spine and heels being covered with eschars. In fatal cases the length of the illness has varied from ten days to six weeks, and death seemed to be due to bulbar paralysis. The signs and symptoms thought to point to botulism have been vomiting, transient facial palsy, transient ptosis, absence of spinal paralysis, drowsiness and absence of fever and constipation, with dryness of the nose and mouth. Although in a considerable number of cases there was a history of the recent consumption of canned food, cheese, bacon, ham and sausages, these and other now exceptional foods had not been consumed in the majority of the cases, and no particular food has been found to be related to the outbreak. So far, no bacteriologic proof is forthcoming that any of the cases were due to bacterial infection or to intoxication by the products of bacterial activity, whether associated with food consumption or not. Against the suggestion of botulism is the fact that a case has been observed in an infant at the breast, and also that thus far *Bacillus botulinus* has not been identified.

Netter[2] insists that the disease cannot be a form of poliomyelitis, stating that this epidemic occurred during the winter and spring months, while poliomyelitis occurs almost always in the autumn; that the majority of persons affected were adults, while poliomyelitis affects mostly children, and that the spinal fluid was normal, which is not the case in poliomyelitis. In the present epidemic there were also few meningeal symptoms, and the mortality was very high —50 per cent. In poliomyelitis the meningeal symptoms are much more marked, and the mortality is much lower—about 11 per cent.

Reviewing the facts in regard to poliomyelitis, we find that epidemics very much similar to the one in question have been reported before. Hence we are probably here dealing with an epidemic of poliomyelitis, though perhaps of a rather unusual distribution in the nervous system. In regard to season, Wickman has reported an epidemic in Sweden lasting through the winter with its maximum in April and May. As to adults, there are great variations; at times the percentage is high and at other times low. An epidemic is reported by Müller, on the island of Nauru, where some 700 cases occurred, the majority of which were in adults.

In regard to the spinal fluid, it is sterile and usually clear in poliomyelitis. There is cellular increase consisting of polymorphonuclears at first and later of lymphocytes; but the cells rapidly disappear from the fluid so that after the first two weeks the count is either normal or nearly so. As to globulin, during the first week it is found in only half of the fluids, and after the third week there is a decrease. Accordingly the condition of the spinal fluid would depend on the time it was examined. At any rate, the question of whether a person may have poliomyelitis without having any changes in the spinal fluid is at present an open one.

The meningeal form of poliomyelitis is, of course, common, and at times the picture of meningitis may be so marked as actually to obscure the real nature of the disease; but there is also the atoxic or asthenic form in which there is drowsiness, stupor, etc., as in the present epidemic. Many of the reported cases, in England at least, have also shown marked meningeal symptoms. The mortality rate varies in the different epidemics of poliomyelitis. The younger children have a better chance for life than the older children and adults. In Wickman's cases the mortality was 27.6 per cent. in persons between 12 and 32 years of age. In one small epidemic he saw a mortality of 42.3 per cent. Lindner and Mally report a mortality of 50 per cent. in persons over 10 years of age. In the New York epidemic in 1916 the fatality rate was 27.2 per cent. in New York City. This tallies closely with the present epidemic in England and France. The various eye symptoms reported indicate an involvement of the third, fourth and sixth cranial nerves; the facial paralysis, involvement of the seventh; and the difficulty in swallowing and affection of the tongue, involvement of the ninth and twelfth. As a matter of fact, these cranial nerves are those most frequently involved in poliomyelitis. In the bulbar form of poliomyelitis, which means localization in the pons and medulla, the combinations of paralyses mentioned are observed.

Further investigations are in progress. From this without doubt we shall learn that this is not a new disease, but that the epidemic is one of poliomyelitis, the cerebral type being predominant, and in many respects both epidemiologically and clinically similar to the New York epidemic of 1916.

Current Comment

THE PRESENT EPIDEMIC OF INFLUENZA

The present epidemic of influenza spreads so rapidly—attacks in a new spot so suddenly—that it is difficult to discuss its incidence at the time THE JOURNAL goes to press without great fear that it will have completely changed by the date of publication. As we write it is reported that cases in the Army camps are decreasing, some 11,750 new cases having been reported in all Army camps during the twenty-four hours ending noon, October 8. New cases of pneumonia have likewise decreased, totaling some 2,181 with a mortality of 781 for the twenty-four hours. At that date the total number of cases of influenza reported from all Army camps since the disease became epidemic was placed at almost 200,000, with some 20,000 pneumonia cases and between 5,000 and 6,000 deaths in the Army alone. The civilian population has likewise suffered greatly, particular points of attack being in the New England states, in Pennsylvania and in Indiana.

◆

As pointed out elsewhere, the great danger is not from influenza, but from secondary complications communicated in the same manner as the influenza itself. Influenza uncomplicated by cross-infection, in the ordinary person, will run its course, and those who have it will recover. The secondary pneumonia is quite infectious and a serious complication, which up to date has occurred in some 10 per cent. of the cases and which has a mortality between 25 and 33⅓ per cent. of all the persons whom it attacks. The prevention of this pneumonia is dependent on a strict isolation of the influenza patient, not so much to protect others against the influenza, but to protect the patient against pneumonia through cross-infection.

◆

In some cases at least an exceedingly rapidly progressing form of pneumonia develops early in the disease, with a great deal of fluid, the lung being only partially consolidated. The patients may die with a great deal of frothy fluid in the bronchi, trachea, throat and nose, practically drowning in their own fluid. In many cases this pneumonia begins practically at the same time as the influenza itself, and it is these cases which proceed to a rapidly fatal termination. At the same time, indications are that other forms of pneumonia likewise occur. In others, the influenza is a simple uncomplicated and rather harmless disease.

◆

An interesting feature of the present epidemic is the change in the attitude of the public toward public health methods. The changes incident to the war have caused the public to accept freely orders and suggestions as to their mode of living. When health authorities place a ban on public gatherings, when they insist that the windows of public conveyances be kept open, when they insist on absolute quarantine in order to stop the spread of the disease, the public is ready to obey, and does obey to the fullest measure. Another feature is the confidence of the public in public health authorities, apparently the result of the intense education of the public in prophylaxis of disease which has been going on during the past decade. Orders concerning the epidemic are received without panic or alarm.

MEDICAL STUDENTS IN THE STUDENTS' ARMY TRAINING CORPS

Authority has finally been secured from the War Department for the transfer of students in the Medical Enlisted Reserve Corps to the Students' Army Training Corps, and full instructions will be issued shortly—after certain details have been arranged. This will affect students in the second, third and fourth years of the medical schools. Those enrolled as freshmen medical students are eligible for the Students' Army Training Corps in such medical schools as have established units, or any medical schools that are connected with universities having such units. This provides for uniforms, housing, board, tuition, and pay of $30 a month, the same as for other students in the Students' Army Training Corps. Premedical students likewise may enter the Students' Army Training Corps if the colleges in which they are students have units. All this, aside from students transferring from the Medical Enlisted Reserve Corps, applies only to registrants on September 12. It is expected that some provision will also be made for students who registered prior to September 12. Those in Class 1 who are not qualified for general military service are eligible for admission to the Students' Army Training Corps, and those belonging to deferred classes, if physically qualified, are eligible to enter the Students' Army Training Corps.

DEVELOPMENT FOR PHYSICALLY DISQUALIFIED STUDENTS

It is reported that between 20 and 25 per cent. of the boys examined for the Students' Army Training Corps in the universities and colleges are failing to meet the physical standards adopted for soldiers. This is due largely to underdevelopment and underweight. These boys therefore fail to gain admission to the Students' Army Training Corps; they are not entitled to wear uniforms, and remain in school as civilians. Boylike, these young fellows in civilian clothes are sensitive, and fear that they may be branded as slackers. It has been suggested that the school authorities recognize this condition and provide for some insignia to distinguish those boys disqualified for physical reasons from those who have made no attempt to qualify. While we do not believe in grownups wearing a badge as a proof of their patriotism, there may be some reason for the wearing of such a badge in these schools. But we suggest that instead of supplying these boys with badges, the school authorities recognize the splendid opportunity and institute a plan for developing these boys so that they may become physically fit to wear the uniform. The ideal thing would be for the individual schools to form Development Corps of those physically disqualified and put them in a uniform adopted by the school itself. This would be a stimulus for the boys to cooperate with the University in attaining physical fitness and promotion to the Students' Army Training Corps.

Medical Mobilization and the War

Appointment in the Medical Reserve Corps and Acceptance of Commission

The important decisions relative to appointment in the Medical Reserve Corps have just been promulgated by the Surgeon-General's Office:

(*a*) Graduates of 1918 will be required to serve one year's internship in a civil hospital before being considered eligible for a commission.

(*b*) No more appointments are being made in the Medical Reserve Corps. All commissions issued are in the United States Army. There is no inactive status in the United States Army, consequently the order to active duty invariably accompanies notices of appointment from the Adjutant - General's Office. The newly appointed officers are given fifteen days in which to comply with the Adjutant - General's orders. A failure to comply or to accept a commission within the specified time will be considered by the Adjutant-General as a declination of commission. The appointment will be cancelled and if the applicant wishes a new appointment it will be necessary for him to be reexamined as for an original appointment.

Surgeon-General Merritte W. Ireland

Physicians Needed by Public Health Service

We again call attention to the fact that the United States Public Health Service is in need of physicians to assist it in carrying out its enlarged work in connection with the health conditions in extracantonment and camp zones. This offers an opportunity for those physicians who want to do war work, and who can not, or do not want to, obtain a commission in the Medical Corps of the Army or Navy. Physicians desiring to help in this work should write to the Surgeon-General of the Public Health Service, Washington, D. C. The Journal is prepared to supply forms on which to make formal application. These forms are for the purpose of indicating the applicant's qualifications, and to show in what way he can be best used—whether in a hospital or in public health and sanitary work. The pay is from $2,000 to $2,500 a year. If quarters and subsidence are furnished, the pay is $1,800 a year. No physical examinations are required other than to ascertain whether the physician is able to perform the duty for which he desires to be appointed. These appointments are as acting assistant surgeons since at this time there is *no* provision for commissions. No examinations are required to qualify. The appointment does not exempt one from the Selective Service Law.

SURGEON-GENERAL MERRITTE W. IRELAND

On October 3 the President sent to the Senate the following nomination: "To be Surgeon-General with the rank of Major-General: Major-General Merritte W. Ireland, M. C., U. S. Army." It may be taken for granted that this nomination will be confirmed by the Senate. The appointment of General Ireland to this position will give general satisfaction to the Medical Department of the Army. The record of General Ireland in the Medical Department is a record of thorough, conscientious service fitting him particularly for the position which he now is to occupy.

He was born at Columbia City, Ind., May 31, 1867, was graduated from the Detroit College of Medicine in 1890, and followed his graduation with an internship in St. Mary's Hospital, Detroit, from 1889 to 1890; was graduated from Jefferson Medical College, Philadelphia, in 1891, immediately afterward entering the service as first lieutenant and assistant surgeon on May 4, 1891. He began his military career at Jefferson Barracks, Mo., on May 27, 1891, on May 4, 1896, he was made captain and assistant surgeon. In the Spanish-American War he served with the Fifth Army Corps in Cuba and later at Camp Wyckoff, N. Y., on April 17, 1899, becoming surgeon with the rank of major of the 45th United States Infantry. At this time he went with his command to the Philippine Islands, serving in several campaigns and being officially commended by the chief surgeon. In April, 1900, he took charge of the medical supply depot of the Division of the Philippines at Manila, and was honorably discharged from volunteer service, June 30, 1900. In 1902 he entered the Surgeon-General's Office, working under Surgeon-General O'Reilly and continuing under Surgeon-General Torney. He was promoted to major and surgeon and to major, M. C., Aug. 3, 1903, and to lieutenant-colonel, May 1, 1911. He left the office of the Surgeon-General in 1912, again going to the Philippines, where he was stationed as post surgeon at Fort William McKinley. He thus had a continuous service in the Surgeon-General's Office of approximately ten years. He returned to the United States and was placed in charge of the base hospital at Fort Sam Houston in 1916, and accompanied General Pershing to Mexico as surgeon of the American Expeditionary Forces to Mexico. When the United States entered the great war he accompanied General Pershing to France as chief surgeon of the American Expeditionary Forces, was promoted to the rank of brigadier-general, May 1, 1918, and more recently to the rank of major-general and Surgeon-General of the expeditionary forces.

Our new Surgeon-General is, therefore, fitted especially to conduct the medical service of the Army through the remainder of the war, as well as in times of peace. He has filled practically every position to which the men who will serve under him may be called—surgeon of volunteers, post surgeon, assistant in the Surgeon-General's Office, supply depot, surgeon-general of the expeditionary forces—a complete record which indicates that the chief will know what confronts each of his subordinates.

BRIGADIER-GENERAL NOBLE TO BE SURGEON-GENERAL FOR EXPEDITIONARY FORCES

Included with the nominations sent to the Senate by the President, October 3, was the appointment of Brig.-Gen. Robert E. Noble to take the place vacated by General Ireland as Surgeon-General for the American Expeditionary Forces.

Major-General Robert E. Noble

General Noble was born in Georgia in 1870. He was educated in the Polytechnic Institute of Alabama, receiving his B.S. degree in 1890 and the M.S. in 1891 and was graduated in medicine by Columbia University in 1899. He was appointed assistant surgeon in 1901, and was an honor graduate of the Army Medical School in 1904, then was appointed captain and assistant surgeon in the Medical Corps, June, 1906, and major in January, 1910. From 1907 to 1914 he served with General Gorgas in the Canal Zone and was efficient in helping to secure the wonderful sanitary results which made the building of the Panama Canal possible. When General Gorgas was made Surgeon-General, Major Noble accompanied him to the Surgeon-General's Office, taking over the personnel department. As chief of the personnel division he was instrumental in building up the large personnel of the Medical Reserve Corps which today constitutes the large majority of the commissioned portion of our Medical Department. Later, in addition to his other duties, he was called to assume the duties of director of hospitals on this side of the Atlantic, and at the time of his present appointment was engaged in completing arrangements for the care of the sick and wounded who are to be returned from Europe, or who may need hospital care in the United States. This is the fundamental work in the Department of Reconstruction and Rehabilitation.

General Noble has had a wide experience in sanitation, and as assistant Surgeon-General is thoroughly acquainted with the administrative work of the Surgeon-General's Office which will be helpful in his new position. In every respect he is well qualified for the new functions and responsibilities he will assume in France as head of the Medical Division of our Expeditionary Forces.

Promotions of Medical Officers

Recent records carry the following promotions: Major-Gen. Merritte W. Ireland (Colonel, M. C.), now holding the emergency rank of Major-General, to be Major-General and Surgeon-General; Brigadier-Gen. Robert E. Noble (Lieutenant-Colonel, M. C.), now holding the emergency rank of Brigadier-General, to be Major-General for the period of the present emergency, for service abroad, succeeding Major-General Ireland as first assistant Surgeon-General; Col. Edward L. Munson to be Brigadier-General for the period of the emergency; Cols. James D. Glennan, William S. Thayer and John M. T. Finney to be Brigadier-Generals, M. C. Lieutenant-colonels, M. C., to colonels, M. C. (emergency), Sept. 4, 1918: E. F. Geddings, Fort Adams, R. I.; G. McD. Van Poole, Honolulu, T. H.; J. F. Hall, Plattsburg Barracks, N. Y.; L. M. Hathaway, Fort Baker, Calif.; A. M. Whaley, Washington, D. C. Majors, M. C., to lieutenant-colonels, M. C. (emergency), Sept. 6, 1918: H. C. Coe, New York; J. B. Carnett, Philadelphia; E. S. Kilgore, San Francisco; A. W. Elting, Albany, N. Y.; W. D. Webb, Washington, D. C.; J. B. Walker, New York; D. D. Lewis, Chicago; E. H. Fiske, Brooklyn; W. M. L. Coplin, Philadelphia; C. L. Chase, Chickamauga, Ga.; S. C. Gurney, Detroit; V. P. Blair, St. Louis; A. Greenwood, Boston. Sept. 7, 1918: J. W. Amesse, Denver; A. E. Cohn, New York; J. J. Dowling, Boston; W. Gillespie, Cincinnati; S. McGuire, Richmond, Va.; G. B. Webb, Colorado Springs, Colo.; W. F. Wesselhoeft, Boston.

Promotions in Medical Corps of the Navy

The following promotions in the Medical Corps of the Navy are announced: As rear admirals, U. S. Navy, medical directors Albert M. D. McCormick and Robert Morris Kennedy; as permanent captains, Surgs. Charles E. Riggs, Ammen Farenholt, Middleton S. Elliott, Frank L. Pleadwell, Dudley N. Carpenter, James C. Pryor and Washington B. Grove; as temporary captains, Surgs. Raymond Spear, John B. Dennis, Eugene J. Grow, Frank E. McCullough, Granville L. Angeny, William H. Bell, Holton C. Curl, Edward G. Parker, Henry E. O'Dell, James S. Taylor, Joseph A. Murphy, Charles E. Freeman, Charles St. J. Butler and John M. Brister.

Appointment in War Risk Bureau

Dr. Edson W. Glidden, 2d, has been appointed assistant medical director of the War Risk Insurance Bureau, Medical Department, in charge of the tuberculosis department. This will interest those who realize how many tuberculous ex-soldiers and sailors are cared for by this bureau. Dr. Glidden was for several years assistant superintendent of the Lakeville Tuberculosis Sanatorium, Middleboro, Mass.

For Addition to the Hygienic Laboratory

A bill is under consideration in Congress for an appropriation of $250,000 to build a much needed addition to the Hygienic Laboratory of the Public Health Service in Washington, D. C., and in the House, a special rule has been brought in making this bill a special order.

COMMISSIONS ACCEPTED, MEDICAL CORPS, U. S. ARMY

Previous lists published in The Journal, June 1, 22 and 29, July 13, 20 and 27, August 3, 10, 17, 24 and 31, September 7, 14, 21 and 28 and October 5.

Honorably discharged on account of physical disability existing prior to entrance into the service, Capts. N. R. CALDWELL, Groton; S. S. MARTIN, Windsor.

Virginia

To Camp Crane, Pa., from Fort Oglethorpe, Lieut. W. S. TUCKER, New Glasgow; from New Haven, Lieut. C. B. COURTNEY, Fairfax.

To Fort Oglethorpe, base hospital, from Newport News, Capt. T. C. FIREBAUGH, Harrisburg.

To report to the commanding general, Philippine Department, from Fort Ontario, Major J. W. HOPE, Hampton.

To Syracuse, N. Y., from Fort Meyer, Major A. G. COOMBE.

Honorably discharged on account of physial disability existing prior to entrance into the service, Lieuts. H. S. SCOTT, Emory; L. B. STATON, Norfolk.

Washington

To Camp Crane, Pa., from Camp Cody, Capt. G. A. GRAY, Spokane.

To Camp Zachary Taylor, Ky., base hospital, from Camp Custer, Lieut. J. S. DAVIES, Tacoma.

To Fort Oglethorpe, evacuation hospital, from Camp Lewis, Lieut. J. HEHIR, Sedro-Wooley.

To Fort Sheridan, Ill., base hospital, from Camp Custer, Lieut. W. H. BOONE, North Yakima.

To Fort Snelling, Minn., base hospital, from Camp Lewis, Lieut. W. F. CUNNINGHAM, Seattle.

The following order has been revoked: *To Camp Kearney, Calif.*, Lieut. C. S. PASCOE, Tacoma.

West Virginia

To Camp Bowie, Texas, base hospital, from Camp Gordon, Capt. C. DENHAM, Weston.

To Camp Crane, Pa., from Fort McPherson, Lieut. B. B. COX, Morgantown.

To Camp Custer, Mich., base hospital, for instruction, Major J. E. CANNADAY, Charleston.

To Camp McClellan, Ala., evacuation hospital, from Fort Sam Houston, Lieut. T. E. VASS, Bluefield.

To Camp Meade, Md., Capt. C. P. SHIRKEY, St. Albans.

To Camp Sevier, S. C., base hospital, Lieut. W. T. OWENS, Clarksburg.

To Fort Oglethorpe for instruction, Capt. G. A. MacQUEEN, Charleston.

Honorably discharged on account of physical disability existing prior to entrance into the service, Lieut. A. E. BAYS, Barboursville.

Wisconsin

To Army Medical School for instruction, from Rantoul, Ill., Lieut. D. L. DAWSON, Rice Lake.

To Camp Abraham Eustis, Va., camp hospital, and on completion *to Boston, Mass.*, Harvard Graduate School of Medicine, for instruction, from Fort Oglethorpe, Capt. J. W. POWERS, Burlington.

To Camp Custer, Mich., from Fort Oglethorpe, Lieut. S. J. SEEGER, Milwaukee. Base hospital, from Camp Sherman, Capt. F. E. ANDRE, Kenosha. Base hospital, for instruction, Lieuts. R. E. FLYNN, La Crosse; H. McCABE, Milwaukee.

To Camp Gordon, Ga., base hospital, from Camp Gordon, Lieut. J. W. HANSEN, Milwaukee.

To Camp Grant, Ill., from Army Medical School, Lieut. C. A. CIBELIUS, Racine.

To Camp Jackson, S. C., base hospital, Capt. S. G. PAKE, Hayward.

To Camp Sherman, Ohio, as sanitary inspector, from Camp Zachary Taylor, Major W. W. PRETTS, Platteville. *To examine the command* for nervous and mental diseases, from Camp Grant, Capt. J. F. WENN, Milwaukee.

To Camp Travis, Texas, from Fort Riley, Capt. F. W. McKEE, Richland Center; Lieut. S. C. McCORKLE, Wallis.

To Fort Benjamin Harrison, base hospital, from Camp Custer, Lieut. V. STARNES, Mauston; from Camp Grant, Lieut. J. B. VEDDER, Marshfield.

To Fort Riley for instruction, Capt. A. J. GATES, Tigerton; Lieut. H. J. GRAMLING, Milwaukee.

Honorably discharged on account of physical disability existing prior to entrance into the service, Lieut. G. F. KENNEY, Milwaukee.

Wyoming

To Fort Benjamin Harrison, base hospital, from Camp Custer, Capt. C. E. HARRIS, Basin; from Fort Riley, Capt. G. A. FOX, Cheyenne.

To New Haven, Conn., from Fort Riley, Capt. M. A. NEWELL, Sheridan.

ORDERS TO OFFICERS OF THE UNITED STATES PUBLIC HEALTH SERVICE

Surg. JOHN McMULLEN, proceed to Nitro, W. Va., for conference relative to treatment of applicants for employment suffering from trachoma.

Surg. G. W. McCOY, represent the service at the meetings of the Laboratory Section of the American Public Health Association at Chicago.

P. A. Surg. F. A. CARMELIA, relieved at Newport News, Va. Proceed to bureau for duty.

P. A. Surg. E. W. SCOTT, relieved at Washington, D. C. Proceed to Rosebank, Staten Island, N. Y., for duty.

P. A. Surg. JOSEPH BOLTEN, relieved at the Hygienic Laboratory. Proceed to the San Francisco Quarantine Station for duty.

P. A. Surg. W. L. TREADWAY, proceed to Nitro, W. Va., and advise regarding installation and operation school medical inspection system.

P. A. Surg. J. G. TOWNSEND, proceed to Ranger and Petrolia, Texas, to supervise sanitary work.

Asst. Surg. W. F. FOX, visit Houston, Texas, to study venereal disease control methods.

Prof. C. W. STILES, proceed to Wilmington, N. C., for duty.

Prof. E. B. PHELPS, proceed to places in the vicinity of Washington to investigate public need of a contemplated improvement.

Pharm. C. H. BIERMAN, proceed to Boston Quarantine Station for temporary duty.

A. A. Surg. O. D. ADAMSON, relieved at Columbia, S. C. Proceed to Fayetteville, N. C., for duty.

A. A. Surg. J. B. ELLIOTT, relieved at Florence, Ala. Proceed to Little Rock, Ark., for duty.

A. A. Surg. ROBERT E. GRAMLING, proceed to Leavenworth, Kan., for duty in venereal control.

A. A. Surg. W. F. REASNER, proceed to Hattiesburg, Miss., for duty.

A. A. Surg. I. P. ROBINSON, relieved at Leavenworth, Kan. Proceed to Washington, D. C.

A. A. Surg. GEORGE W. SHIRK, proceed to Houston, Texas, for duty in venereal disease control.

San. Eng. H. W. STREETER, proceed to Cincinnati and Lima, Ohio, to investigate public health value of contemplated improvements.

Asst. San. Eng. H. F. S. TAIT, proceed to Shreveport, La., to investigate public health value of contemplated improvement.

Asst. Epid. C. C. APPLEWHITE, relieved at Englewood, N. J. Proceed to Atlanta, Ga., for duty.

Scien. Asst. SAMUEL SAUNDERS, Jr., assume charge of health activities in Brunswick and Glenn County, Ga.

Asst. Director DAVID ROBINSON, proceed to Philadelphia and confer with the State Counsel of National Defense concerning venereal control measures.

Surg. J. GOLDBERGER, directed to proceed to New England and other states to undertake studies in regard to the etiology of influenza with special reference to its transmission.

Surg. L. P. H. BAHRENBERG, deliver an address at the Missouri Baptist state convention at Fulton, Mo., Oct. 22, 1918.

P. A. Surg. H. J. WARNER, relieved at Atlanta, Ga., proceed to Ellis Island, N. Y.

P. A. Surg. W. F. DRAPER, proceed to Boston, Mass., to assume charge of Service operations in connection with control of epidemic diseases.

P. A. Surg. G. A. KEMPF, proceed to Boston, Mass., for duty in the suppression of influenza.

P. A. Surg. J. H. LINSON, proceed to Boston, Mass., for duty in the suppression of influenza.

Asst. Surg. H. C. YARBROUGH, proceed to the Reedy Island Quarantine Station for temporary duty.

Asst. Surg. T. B. H. ANDERSON, proceed to Wichita and other points in the state of Kansas for duty in inaugurating venereal disease clinics.

Asst. Surg. C. R. ESKEY, relieved at Montgomery, Ala., proceed to Boston, Mass., for duty in the suppression of influenza.

Asst. Surg. CHARLES ARMSTRONG, proceed to Boston, Mass., for duty in the suppression of influenza.

Asst. Surg. R. E. DYER, proceed to Boston, Mass., for duty in the suppression of influenza.

Asst. Surg. J. K. FULLER, proceed to Boston, Mass., for duty in the suppression of influenza.

Asst. Surg. R. P. SANDIDGE, relieved at Louisville, Ky., proceed to Boston, Mass., for duty in the suppression of influenza.

A. A. Surg. D. A. BUCK, relieved at Baltimore, Md., proceed to Norfolk, Va., for duty.

A. A. Surg. W. C. EDMUNDS, proceed to Boston, Mass., for duty in the suppression of influenza.

A. A. Surg. F. F. FARNSWORTH, attend the meeting of the American Public Health Association at Chicago, Ill., Oct. 14-17, 1918.

A. A. Surg. ARTHUR R. PILLSBURY, proceed to Boston, Mass., for duty in connection with venereal disease control measures.

A. A. Surg. STAFFORD B. SMITH, proceed to New York City for duty in venereal disease control measures.

A. A. Surg. ABRAHAM TRUMPER, relieved at San Antonio, Texas, proceed to Montgomery, Ala., for duty in extracantonment sanitation.

A. A. Surg. W. A. WILSON, proceed to various places in the state of New York for duty in connection with venereal disease control.

Medical News

(Physicians will confer a favor by sending for this department items of news of more or less general interest; such as relate to society activities, new hospitals, education, public health, etc.)

ARKANSAS

Medical Society Meeting Deferred.—After a consultation with the executive officers of the Third District Medical Society, it was decided to defer the annual meeting until next year because of the disturbed conditions in the profession. The meeting was to have been held at Lonoke.

Quarantined on Account of Influenza.—The town of Carlisle was quarantined, September 24, on the order of Dr. Jacob C. Geiger of the United States Public Health Service, on account of influenza, of which there were 125 cases on that date. The epidemic was traced to two sailors who had come to Carlisle on furlough from Boston. Lieut. A. M. Jones of the medical service was placed in charge of the situation by Dr. Geiger.

CALIFORNIA

Personal.—Dr. J. Perry Lewis, San Diego, who has been seriously ill is reported to be convalescent.——E. H. Meyers, Napa, is reported to have been found guilty of violating the Harrison Narcotic Law, and is said to have been ordered to pay a fine of $200 or as an alternative to be imprisoned for fifty days in the county jail.

GEORGIA

Personal.—Dr. Jarrett W. Palmer, Ailey, has been appointed a member of the state board of medical examiners for a term of four years, from September 1.

Hospital Annex Opened.—The annex to the Savannah Marine Hospital, located in the former home of Dr. William Duncan, East Oglethorpe, was opened, September 16, with accommodation for twenty-four patients.

Sanatorium Sold.—The Williams Private Sanatorium, Macon, founded by the late Dr. Howard J. Williams, formerly president of the state board of health, has been sold to Drs. Max Jackson, Olin H. Weaver, Thomas D. Walker, Jr., and Charles H. Richardson, Jr. The sanatorium will be operated under its original name.

ILLINOIS

Practicing Without a License.—Six midwives who were practicing in Joliet without a license were arrested and each of them fined $100 and costs, recently, by the Department of Registration and Education of the State of Illinois.

Infantile Paralysis.—During July and August 125 cases of infantile paralysis were reported to the state department of health from thirty counties in Illinois. Of these cases forty-seven were reported from Cook, thirteen from Kankakee and ten from Jo Daviess County.

Mandamus Petition Denied.—A report from the Department of Registration and Education of Illinois states that Judge Hebel has declined to grant the petition of the Chicago Hospital College of Medicine for mandamus against the department to compel restoration of good standing.

Personal.—Dr. H. Eugene Delavergne, Belvidere, secretary of the Boone County Medical Society, is about to move to Kankakee. The Boone County Medical Society at a meeting, September 25, presented Dr. Delavergne with a mahogany office chair.——Dr. Robert C. Mitchell, Belvidere, has been elected secretary of the Boone County Medical Society.——Dr. Philip F. Gillette, Elgin, has returned to his old position as assistant physician to the Elgin State Hospital.——Dr. Frazier N. Cloyd, Danville, has been appointed surgeon for the New York Central Lines, to succeed Dr. George L. Williamson, Danville.

Chicago

Medical College Not Suspended.—The statement published, October 5, saying that the Hahnemann Medical College and Hospital of Chicago has suspended for the duration of the war and which appeared to be based on good authority has proved to be incorrect. The college has recently received authority from the government to establish a unit in the Students' Army Training Corps.

Personal.—Dr. Henry F. Lewis resigned, September 30, as professor and head of the department of obstetrics and gynecology in the School of Medicine of Loyola University.——Dr. John E. Macklin has been commissioned captain, C. A. M. C., and has been assigned to temporary duty at the Willows Camp, Victoria, B. C.——Lieut.-Col. Ernest E. Irons, M. C., U. S. Army, on duty at Camp Custer, Mich., is reported to be ill with influenza.——Major Edmund J. Doering, M. C., U. S. Army, president of the local board of examiners for the Medical Corps of the Army, has been promoted to the rank of lieutenant-colonel.——Dr. Adolphe R. Caron has been operated on in the Passavant Hospital. He expects to enter Red Cross service in France.——Dr. H. I. Davis has been commissioned for service with the American Red Cross in France.

Illegal Practitioners Arrested.—The following violators of the Medical Practice Act, all residing in Chicago, were arrested by the Department of Registration and Education of the State of Illinois, and fined the amounts stated:

David Reeder, 5039 Cottage Grove Avenue, $25 and costs. Mr. Reeder informed the court that he was leaving Illinois for Indiana, his home state.

M. Szxzepkowski, 1610 N. LaSalle St., $25 and costs.

Roman Tzumalski 1600 N. LaSalle St., $25 and costs.

Stan Kierzek, 4758 Justine St., case dismissed on payment of costs amounting to $8.50.

Madion M. Ormsby, 20 S. Clark St., turned over to the probation court and an officer appointed to look after him. Ormsby is 76 years old and very feeble.

Michael Crawczyk, $25 and costs on a charge of violating the medical practice act by treating Charles Zuraj without a license.

MARYLAND

Personal.—Dr. Alma Rothholz, who has distinguished herself as a war worker in France, has been requested by Queen Elizabeth of Belgium to take charge of a hospital near the front for the babies of Belgium. The mission of the institution is to provide medical attention for all the babies of that stricken country.

State Hospital Train in Public Health Service.—Following a request from Surgeon-General Blue, made through the Public Health Service, the Maryland State Hospital Train was sent in less than eleven hours after the call was received to Fall River, Mass., to combat the spread of the influenza. This is the first time the train has been put into service since its equipment. The train was ready very soon after the request was received, but its departure was held up by the fact that physicians and nurses, now very scarce, could not be secured on time. Ten nurses, six from the Union Protestant Infirmary and four from the University Hospital, responded to the call and the following physicians were secured: Drs. Edgar M. Parlett, Baltimore, Calvin N. Gabriel, John W. Abbott and Thomas C. Worthington. Dr. Daniel Z. Dunott, chief surgeon of the Western Maryland Railroad, is in charge of the train.

MINNESOTA

Health Merger Bill.—At a meeting in the office of Hennepin County Medical Society, Minneapolis, September 18, the consolidation of all public health organizations under a single head was discussed. A bill providing for this consolidation will go before the state legislature this fall. The mayor and five members of the city council will be members of the board.

Personal.—Dr. Gustav A. Renz, assistant city health officer of St. Paul, who has been ill at St. Joseph's Hospital, has recovered and assumed practice.——Dr. John Sundwall, Lawrence, Kan., has been appointed health commissioner of the University of Minnesota.——A medical military unit is being formed at Rochester with Dr. Frederick L. Smith as captain and Dr. Willis S. Lemon as first lieutenant.

Course in Public Health Nursing.—The University School for Nurses at the request of the Minnesota Public Health Association, according to the weekly journal of that association for September 26, has determined to provide a four months' intensive course in public health nursing for graduates and to accredited schools of nursing for the benefit of their senior students. It has been the aim of the university school to establish a regular course in this work, but the exigencies of the war have delayed this action.

Tuberculosis Clinics.—A rural clinic was held at Fertile, September 25, by Dr. Charles H. Cole, medical director of Sunny Rest Sanatorium, Crookston, under the auspices of the advisory commission of the State Sanatorium for Consumptives. At this clinic twenty-two persons presented themselves for examination and twelve of these cases were referred to the sanatorium. Regular clinics are held every Tuesday at the Sunny Rest Sanatorium and every Thursday at Oakland Park Sanatorium, Thief River Falls, of which Dr. Cole is also medical director. At these clinics from four to eight persons come for examination each week.——A tuberculosis clinic in Renville County was held at the County Court House, Olivia, September 30, from 11 a. m. to 1 p. m., and from 3 p. m. to 6 p. m., under the charge of Dr. Abraham P. Terk of Riverside Sanatorium, Granite Falls.——A free tuberculosis clinic was conducted at the office of the health department of Eveleth, September 12, by Dr. Arthur T. Laird of Nopeming Sanatorium.——The antituberculosis committee of the Minneapolis Associated Charities at its annual meeting, September 20, voted to expend $18,000 during the coming year toward the assistance of the Red Cross in caring for returned soldiers suffering from tuberculosis; for the establishment of a Childrens' Preventorium to be located at Glen Lake; for tuberculosis dispensaries to be located in settlement houses; for two physicians to be added to the force in charge of tuberculosis clinics, and for the salary of a nurse to be added to the nurse force of the tuberculosis division of the city health department.

MONTANA

Hospital Cornerstone Laid.—The cornerstone of the new St. Vincent's Hospital, Billings, was laid with appropriate ceremonies, September 29. The building will cost about $400,000.

The Handling of Venereal Diseases.—At a meeting of the state board of health two new divisions were created for the handling of venereal diseases under the government plan. One division will have charge of the enforcement of rules and regulations, and the other will handle the publicity and education.

Personal.—Dr. John M. Scanland, superintendent of the State Hospital for the Insane, Warm Springs, has been commissioned captain, M. C., U. S. Army.——Dr. A. P. Stevenson, Roundup, has been appointed health officer of Musselshell County, to succeed Dr. George A. Lewis, who has resigned to enter the military service.——Dr. Oscar M. Lanstrum, Helena, has won the republican nomination for United States Senator from Montana.

NEBRASKA

Social Morality.—Dr. Abby Virginia Holmes, Omaha, is disposing of her practice and will devote her entire time to lectures on social morality and sex education in colleges and universities and also in communities adjacent to training camps.

Personal.—Dr. Albert P. Fitzsimmons, formerly of Tecumseh, but now treasurer of the Philippine Islands, is paying a visit to his old home.——Dr. Edward A. Hudson, Edison, is seriously ill as the result of a cerebral hemorrhage.——Dr. George M. White, Ingleside, has been appointed assistant superintendent of the Ingleside State Hospital.——Dr. Wilford H. Crutcher, superintendent of the State Orthopedic Hospital, Lincoln, has resigned to enter the military service.——Dr. Dellizon A. Foote, Omaha, was operated on at Rochester, Minn., September 18, and is reported to be doing well.——Dr. Charles W. Ervin, Lincoln, has been appointed assistant adjutant-general of the state.——Dr. Beverly A. Finkle, assistant superintendent of the Norfolk State Hospital, has been appointed superintendent of the State Orthopedic Hospital, Lincoln.——Dr. Lawrence B. Pilsbury, superintendent of the Lincoln State Hospital, has resigned to enter the military service.

NEW JERSEY

Centennial of Medical Society.—The Gloucester County Medical Society celebrated its one hundredth anniversary at Winona, September 19. The twenty-nine members of the organization were all present, together with invited guests.

Influenza at Gloucester City.—According to the board of health records of Gloucester City there were, October 4, 3,000 cases of influenza, of which 300 had developed pneumonia. The situation in the shipyards was a serious one, 600 workers being ill. Dr. D. C. Bowen of the state board of health made a survey and telephoned to the National Red Cross headquarters at Washington for six trained nurses. Three additional physicians were secured and another hospital, in the auditorium of the city hall, was opened. At Pusey and Jones (shipyards) twenty-five patients were in the temporary hospital.

Personal.—Dr. Irwin W. Kirk has been elected city physician of Millville to succeed Dr. Charles H. Mayhew, who has resigned to enter the military service.——Dr. Norman S. Garrison, Rutherford, has been elected medical inspector for the Deerfield and Lawrence township schools.——Dr. W. S. Jones, Trenton, has resigned as a member of the State Board of Charities and Correction to become commandant of the Soldiers' and Sailors' Home at Vineland.——Under the adjustment made by the state board of health, Dr. Henry A. Cotton has withdrawn his resignation as medical director of the Trenton State Hospital and will resume his duties with an increase in salary from $4,500 to $6,000 a year.

NEW YORK

The Home Touch for Medical Officers.—The Onondaga County Medical Society has issued a monthly publication known as *The Bulletin*, which will contain news items of interest to medical officers from that part of the state on duty with the American Expeditionary Forces, and so will keep them in touch with local events of interest.

Personal.—Dr. Frank Vander Bogart, Schenectady, has been appointed medical supervisor of child welfare work with the American Red Cross in Italy.——Dr. Franklin C. Gram, acting health commissioner of Buffalo, has been commissioned captain, M. C., N. Y. State Guard, and has been assigned to duty with the 65th Infantry.——Major William G. Bissell, Buffalo, M. C., N. Y. State Guard, assigned to duty with the 65th Infantry, has been selected as professor of military hygiene and sanitation in the student course to be given under the auspices of the War Department at Canisius College.

New York City

Personal.—Dr. Elbert M. Somers, Brooklyn, has entered the service of the American Red Cross as hospital superintendent in France.

Harvey Society Lecture.—The first lecture of the Harvey Society course will be given, October 19, at 8:30 p. m., by Dr. Edward K. Dunham, on "Certain Aspects of the Application of Antiseptics in Military Practice."

OHIO

Physician Fined.—Dr. Julius P. Haynes, a colored practitioner of Toledo charged with illegally furnishing habit-forming drugs, is reported to have pleaded guilty in the probate court, and to have been fined $100 and costs.

Personal.—Dr. Henry C. Eyman, because of age and failing health, has resigned as superintendent of the Massillon State Hospital after thirty-four years' continuous service in state hospitals, and has been succeeded by Dr. Arthur G. Hayde, who has been for several years superintendent of the Cleveland State Hospital.——Dr. Charles E. Sawyer, Marion, chairman of the War Savings Campaign, has been presented by the Ohio War Savings Committee with a gold medal for distinguished service.——Dr. Francis A. McCullough, Mansfield, who was operated on at the Protestant Hospital, recently, is reported to be convalescent.

Miscellaneous Health Activities.—An inspector of the state department of health reports that at Canton there are five times as many cases of tuberculosis as are being cared for or receiving attention from public health nurses. There are also many cases of trachoma in the city.——The state department has joined the United States Public Health Service in recommending that smallpox vaccination and antityphoid inoculation be required of all employees in industrial plants, on the ground that the protection of the health of employees making war munitions is just as important as that of the soldiers in the field.——The department has adopted the plan of checking disease reports against death reports to obtain evidence against physicians who fail to report communicable diseases. In this manner eleven unreported cases of typhoid fever were discovered in June. Local health departments are urged to follow a like plan with reference to reports of communicable diseases.

Recent Gifts Toward Western Reserve University Medical Group.—Two years ago a plot of land which approximated 15 acres in extent, known as the Ford Estate, was purchased as a site for the new buildings of the Medical Department of Western Reserve University and for a new Lakeside Hospital, for a babies' and for a maternity hospital. It was the plan to create a group of hospital buildings combined with the medical school to make an ideal teaching plant for the teaching of medicine. This tract is situated next to the literary departments of Western Reserve University and the Case School of Applied Science. Although the war has postponed the erection of any of these buildings, Lakeside Hospital lately received some noteworthy contributions and bequests which will materially hasten the buildings. By the will of the late Col. Oliver Payne a large and generous gift of $1,000,000 came to Lakeside to be used at the discretion of the trustees. By the will of the late Mr. W. S. Tyler, Cleveland, a trustee of Lakeside, a bequest of $200,000 was provided to be applied toward the erection and endowment of a maternity ward on the new site. Mr. Samuel Mather, president of Lakeside, opened the new building fund of the hospital by a gift of $350,000. There is also a fund held by the trustees of Lakeside for the benefit of the children's and maternity wards amounting to something over $150,000.

PENNSYLVANIA

Tuberculosis Dispensaries Close.—Dr. B. Franklin Royer, Harrisburg, acting state commissioner of health, has ordered all the 120 tuberculosis dispensaries of the department of health closed so that the nurses may be used in the general epidemic work. This is the first time in the history of the department that it has been necessary to take such a step.

Epidemic Increasing.—October 4, at Harrisburg three deaths and 1,000 cases of influenza were announced by the local board of health. Six hundred cases had been reported during the previous twenty-four hours. Churches and schools were closed.——Bethlehem reported 125 new cases within the twenty-four hours ending October 4.——No cases were reported at Lebanon, but the city was closed as a preventive measure.——In Pittsburgh, moving picture and other theaters and all public meeting places, were closed. October 4, all Liberty Loan and other public meetings were prohibited. The universities, where the students of the Army Training Corps are located, were placed under guard to insure strict quarantine.

Personal.—Dr. Samuel G. Foster, Franklin, was taken ill while performing an operation, September 18, but is now reported to be improving.——Dr. William F. Doyle, Pottsville, is ill at his home with pneumonia.——Dr. Granville H. Walker, Bellevue, who has been seriously ill at his home, is reported to be improved.——Dr. Charles M. Rickert, Millersburg, has been appointed assistant chief medical inspector for the state department of health, to succeed Dr. John J. Mullowney.——Dr. Charles J. Swalm has been elected medical inspector by the Conshohocken School Board.——Dr. Mariam E. K. Frisbie, South Williamsport, has been appointed medical supervisor of the State Hospital, Somerset, to succeed Dr. John S. Marian, who has resigned to enter the military service.

Philadelphia

Campaign for Roosevelt Hospital.—The members of the staff of the Roosevelt Hospital and their friends, September 24, began a campaign to raise $300,000, the amount needed to erect a larger, modern and fully equipped hospital in the district served by the hospital for the last fifteen years.

Beds for Sailors Endowed.—Thirty-five beds for sailors have been endowed at St. Francis Country House at Darby, which has been selected by the government as a convalescent home for men in the service. Many of these beds, the endowment of which is $100, have been given in the name of some American, who has given his life for this country.

Sails for France.—Dr. Caroline M. Purnell has sailed for France as a member of the second unit, American Women's Hospital. Dr. Purnell is also special commissioner in the American Women's Hospital in France, and her mission is to inspect the medical hospitals, and consult with the French authorities and American Red Cross, and survey the field generally.

Personal.—Dr. John A. Kolmer, who has been conducting an investigation of influenza at his laboratory in the Philadelphia Hospital, has been stricken with the disease and is confined to his home.——The following municipal appointments have been announced: Dr. T. Ruth Hartley, special inspector, board of health; Drs. Katherine Radley, Rose Harrison and Samuel Friedenburg, school medical inspectors.

Influenza Epidemic Increasing.—Within the twenty-four hours, ending at noon, October 5, 1,480 new cases had been reported with 159 deaths directly due to the influenza. In the week ending at noon, October 4, there were reported in the city 1,191 deaths from all causes. Of this number 399 were directly chargeable to influenza, 330 being adults and 69 minors. Pneumonia was the cause of the death of 229 persons, of whom 45 were minors and 184 adults; while bronchopneumonia was responsible for the death of 79 persons of whom 44 were adults and 35 minors.——By order of the board of health all schools and churches have been closed, public gatherings prohibited and the sale of liquor stopped throughout the city. Hotels, restaurants, cafes and all political clubs have been ordered to close their bars by the department of health, and retail drug stores have been permitted to sell spirituous and malt liquors only on presentation of a doctor's prescription.

VERMONT

State Society Meeting Postponed.—By order of the state board of health the program for the annual meeting of the Vermont State Medical Society, which was to have been held October 10 and 11, has been postponed.

CANADA

Canadian Medical Protective Association.—The report of the annual transactions of this body has recently been mailed to all members. The report of counsel stated that the association had been called on during the past year to assist some ten members in defending suits for alleged malpractice; in three, action has not been proceeded with; in another the plaintiff withdrew his case, and in still another the plaintiff withdrew and admitted that the conduct of his medical man had been satisfactory. No case of a serious charge against a member occurred.

Medical Society News.—The Academy of Medicine, Toronto, opened for the season, October 1, when Col. Alexander Primrose, C.B., delivered the presidential address.——The Aesculapian Club, Toronto, held its first regular meeting, Thursday evening, October 10, under the presidency of Dr. Harry B. Anderson. The Rev. Canon Gould, M.D., thirteen years a medical missionary in Palestine and Arabia, gave an address on "Palestine and Arabian Factors in the Allied Cause."——At the first open meeting of the Peterborough (Ont.) Medical Society, the evening of October 3, Drs. Richard A. Reeve and Harry B. Anderson, Toronto, were present and delivered addresses.

Blind in Canada.—There are said to be about 700 blind persons in Canada; two-thirds of these lost their sight after reaching 21 years of age. There are five schools for the blind in the dominion with more than 306 pupils. At the present time there are about eighty blinded soldiers. Recently the Canadian National Institute has been incorporated for the purpose of helping the blind. The ways they will be helped are in industrial training, with workshops and other necessary offices. It is believed that $100,000 will be required for the first year's work and $70,000 for the second. Among the blind members of this institute are Dr. Charles R. Dickson, the eminent Canadian electrotherapeutist, and Dr. Thomas Milroy, Winnipeg, Man.

GENERAL

Railway Surgeons to Meet.—The twenty-eighth annual meeting of the New York and New England Association of Railway Surgeons will be held at Hotel McAlpin, New York City, October 21, under the presidency of Dr. James S. Hill, Bellows Falls, Vt.

Dies After Long Service.—Sergt. First Class, David Robertson, Medical Department, U. S. Army, 85 years of age, who had served for sixty-four consecutive years on Governors Island, N. Y., died at his quarters, August 13, from cancer of the intestine and right kidney.

Appropriation for Combating Influenza.—Both the House and Senate have passed House Joint Resolution 333 appropriating $1,000,000 to be expended by the Public Health Service in combating influenza in the present epidemic and other communicable diseases. The money will be available until June 1, 1919, and the work is to be done in conjunction with the medical services of the Army and Navy.

Bequests and Donations.—The following bequests and donations have recently been announced:

Toronto General Hospital, $2,000 for the endowment of a bed; Hospital for Sick Children, $2,000 for the endowment of a bed, contributed by Miss W. J. Barr, Toronto.

Hahnemann Hospital and Philadelphia Home for Incurables, each $5,000 by the will of Mrs. Mary Stotesbury Crozier.

Burlington County Hospital, Mount Holly, N. J., $500, and Friends' Asylum, Frankfort, a sum for the erection of a memorial cottage, by the will of Margaret H. Jones.

Physicians of Southwest to Meet.—At the annual meeting of the Medical Association of the Southwest to be held in Dallas, October 15 to 17, under the presidency of Dr. Edward H. Martin, Hot Springs, Ark., a special war program will be presented. Lieut.-Col. Harry Mock of the Surgeon-General's Office will speak on "The Reconstruction Work as Planned by the Government." The American Red Cross, the Public Health Service, the Pure Food Department and the Council of National Defense will also be represented at the meeting.

Tuberculosis Conference.—The North Atlantic Tuberculosis Conference, representing the states of New York, New Jersey, Pennsylvania, Delaware, District of Columbia, Maryland, Virginia and West Virginia, will be held at the William Penn Hotel, Pittsburgh, October 17 and 18, under the auspices of the National Tuberculosis Association. Dr. Thomas McCrae, Philadelphia, is president, and the program is in the main devoted to the discussion of tuberculosis war problems. The chief topics announced are: "Health Education of the Civilian Population in War Times," "The Need of Adequate Tuberculosis Programs in War Times," and "Adequate Care of Tuberculous Soldiers."

Meeting of American Public Health Association.—The annual meeting of the American Public Health Association will be held at the Hotel Morrison, Chicago, October 14 to 17. There are six sections and a general meeting. The president is Dr. Charles J. C. O. Hastings of Toronto. In the sociologic section there will be interesting round table discussions on the effect of the high cost of living on the public health, the relation of wages to public health, the reconstruction of hospital and dispensary organizations for increased social efficiency, and a discussion on what adjustment in health administration must be made as a result of war conditions. Among the speakers slated to be present are Surg.-Gen. William C. Gorgas, Col. Victor C. Vaughan and Major William H. Welch of the Army Medical Corps, and President George E. Vincent of the Rockefeller Foundation. Surg.-Gen. Rupert Blue of the Public Health Service has also agreed to be present and will discuss President Wilson's executive order placing special war health activities as affecting the civilian population under the supervision of the Secretary of the Treasury. The entire session, Tuesday evening, October 15, will be devoted to the discussion of these war measures. The preliminary program of the meeting will be found in full in *Public Health Reports,* Sept. 20, 1918, and the war program of the Public Health Service, which is to be presented for discussion at the meeting, will be found in *Public Health Reports,* Sept. 27, 1918.

FOREIGN

Deaths in the Profession Abroad.—Dr. **R. Saundby,** emeritus professor of medicine at the University of Birmingham, a former president of the British Medical Association, aged 79. His book on medical ethics reached a second edition in 1907, and he had a wide reputation as a clinician, administrator and author.——Dr. **Margaret Todd,** medical officer to the Edinburgh Hospital for Women and Children, known as a writer under the pseudonym "Graham Travers."——Dr. **J. Vera,** a neurologist and alienist of Madrid, member of the board of the Beneficencia provincial.——Dr. **A. Mendoza,** the pioneer in microphotography in Spain, chief of the laboratory of the Beneficencia provincial and of the scientific institute in charge of Cajal. He took a prominent part in stamping out epidemics of cholera in 1884 and later.

SOUTH AND CENTRAL AMERICA, MEXICO AND WEST INDIES

Circulating Library Founded to Add to Hospital Fund.—At Bogota a circulating library has been founded to aid Hospital San José. Books are donated and the fees for circulation are given to the hospital.

Elections of Officers.—The Sociedad de Cirugia of Bogota at its recent annual meeting elected Drs. L. C. Marquez, president; M. Rueda, secretary, and Dr. H. Machado, director of the work of the Hospital de San Jose.——The Sociedad de Pediatria elected Dr. J. M. Montoya, president, and Dr. J. Bejarano, secretary. The Club Medico, Dr. M. A. Iriarte, president; Dr. C. J. Lopez, secretary.

Buildings for the Medical School in Colombia.—The *Repertorio* of Bogota hails the inauguration of the new pavillions for the study of anatomy, histology and pathologic anatomy, which are to serve as the basis for the equipment for the study of medicine in the republic of Colombia. It states that a new era for the study of medicine is opening in the country, and the men who are to be thanked for it are Drs. L. C. Marquez, president of the Academia Nacional de Medicina, H. Machado, rector of the medical faculty, and P. Martinez. They have accomplished what others regarded as a dream incapable of realization.

MEXICO LETTER

Mexico City, Sept. 23, 1918.

Eighth Anniversary of Founding of University

As yesterday was the eighth anniversary of the founding of the National University here, it was celebrated with a musical-literary ceremony in the morning, in the amphitheater of the National Preparatory School, attended by all connected with the university. Addresses were made by the rector of the university, Dr. J. N. Macies, who spoke in Latin. After these ceremonies a portrait of the late Dr. J. E. Liz, LL.D., who was the first rector of the university, was placed in the rector's office.

At noon a banquet with 150 covers was served in the Chapultepec restaurant, the rector presiding, with the members of the university faculties, the professors and a number of alumni. Among the guests were Mr. H. P. Fletcher, the ambassador from the United States, the Duke de Amalfi, the minister from Spain, and also the ministers from Uruguay and Nicaragua, the president of the city council, and other dignitaries. The culminating note of the conviviality was the toast that the American ambassador offered, expressing his desire to work for the interchange of university professors and students between Mexico and the United States. Señor Fletcher's address, frank, loyal and cordial, elicited enthusiastic "vivas" for the American Union, Spain and President Wilson.

The National University of Mexico was founded under the auspices and patronage of the Universities of California, Oviedo (Spain) and Paris.

Regulation of the Practice of Medicine

The legislature of the state of Jalisco has passed laws regulating the practice of the profession in that state. Before entering on practice in Jalisco, a professional degree is now required of lawyers, physicians, pharmacists, engineers, veterinarians, obstetricians and dentists. These requirements are to be enforced under penalty of fine or imprisonment, except that at points where there are no qualified persons the practice of lay persons will be tolerated. Holders of degrees from foreign schools will have to present their diplomas for verification or submit to an examination. The president of the state has not yet signed the law. Jalisco is the first state in Mexico to enact any law of the kind in this matter, which is of such transcendental social importance. Elsewhere in the country there are no legal restrictions on the practice of unqualified practitioners of medicine and other professions.

Personal

At the request of the rector of the National University, Dr. N. Leon has been appointed the representative of Mexico in the Congreso de Americanistas, which is to convene at Rio de Janeiro in June, 1919. Dr. Leon is professor of anthropology at the National Museum, and has been the official representative of Mexico at various American international gatherings. He is a pupil of Prof. A. Hrdlicka of Washington, and is known in the scientific circles of the American Union.

Dr. T. G. Perrin has been elected a member of the Pedro Escobedo Medical Society, and his inaugural address was entitled "Our Attempts at Bacteriotherapy." It made a good impression. Dr. Perrin is a pupil of Cajal, and is a distinguished Spanish pathologist and bacteriologist who has been residing here for several years.

Dr. F. C. Najera has returned from New York, where he has been on an official commission, and has resumed charge of the Juarez Hospital.

BUENOS AIRES LETTER

Buenos Aires, Aug. 24, 1918.

Epidemic of Typhus

The sanitary commission in charge of Professor Kraus of this city has established the existence of an epidemic of typhus in the provinces of Salta and Jujuy. In 1916 a commission, composed of Drs. Neiva and Barbará, had observed a clinical case and collected data testifying to the existence of this disease, until then not known certainly in Argentina, although it is known in Peru, Bolivia and Chile. Before this there had been only a suspicion of the existence in Argentina of a small epidemic among some recently arrived Russians a few years ago. The data collected by the commission now prove that typhus exists in almost an endemic form in the mountainous and scantily populated provinces of Salta and Jujuy. In the town of Molinos there have been numerous cases, with fourteen deaths among the sixty cases encountered by Dr. Fernandez who was sent to combat the epidemic. At Mendieta (Jujuy) there were four deaths in nine cases, but the general mortality to date seems to have been about 20 per cent. The reason why this disease has not been recognized before was because the endemic foci are in such remote and almost uninhabited regions far from the towns and railroads.

Changes in University Staffs

The conflict that has been going on in the University of Cordoba has grown more acute. The rector and several of the members of the faculties have presented their resignations. The head of the national government has appointed the minister of public instruction to take charge of the matter personally, and reorganize the staff of the university. At the request of the minister of public instruction, the medical faculty of the university of Buenos Aires did not appoint a new dean at the close of the term of office of Dr. Bazterrica, and this post is filled provisionally by the member of the university council who has been longest in office, Dr. E. Canton, until the reorganization of the university statutes has been sanctioned.

Professor of Pathologic Anatomy

Dr. J. Llambias, at present the *intendente municipal* of the city of Buenos Aires, has been appointed professor of pathologic anatomy in the faculty of medicine of the University of Buenos Aires.

PARIS LETTER

Paris, September 12, 1918.

Campaign Against Malaria

In a previous letter mention was made of an important communication by Dr. Marchoux, physician-in-chief of the Place de Paris, on the campaign against malaria (The Journal, Sept. 15, 1917, p. 926). Marchoux insisted particularly on the fact that systematic microscopic examinations of the blood would reveal the parasites of malaria two or three days before the appearance of the febrile attack, and the patient could then be sterilized by the administration of a few grams of quinin. As a matter of fact, hospitalization is not the solution of the question, for the majority of malaria patients need care only during the paroxysms, which occur at irregular intervals. The hospitals should not be filled up by men who do not need constant care. On the other hand, these men cannot be returned to military duty because they may be incapacitated by an attack at any time. The solution of this problem has been found by the creation of the antimalaria dispensary of the Pasteur Institute. This dispensary will keep these patients under observation during the period of development of the hématozoon, making frequent examinations of the blood, so that the appearance of the next paroxysm may be anticipated and be prevented by a prophylactic dose of quinin. If it is possible to check the paroxysms and the multiplication of the hematozoon which is the direct cause of the attack, the patient will have to deal with only one generation of hematozoa, diminished in numbers and in virulence, and thus an important step toward a cure will have been taken.

The dispensary has been installed in a large hall of the hospital of the *centre de réforme* at Vaugirard. It is provided with a series of small stalls separated by wooden partitions, and here come, at the day and hour specified, the patients who are under treatment. The microscopic examination of the blood is made by a group of young army physicians who are specializing in this work. All the other work which is to be done in this department is assigned to Red Cross nurses. Ordinarily a blood examination would consume much time, but by resorting to the so-called "thick drop" method, *la goutte épaisse*, with the hemoglobin removed, first proposed by Ronald Ross and perfected by Tribondeau, these examinations can be made very quickly.

The essential feature of this antimalaria dispensary is the fact that the patient is not hospitalized. The Service de Santé is not put to any expense. The malarial soldier is placed where he can be of most service; he may be placed in the auxiliary service, but, as a rule, he works at his trade in Paris. Therefore, he is not unproductive during the course of his treatment.

Campaign Against Poisonous Gases

For the purpose of instituting proper measures to combat the toxic or poisonous gases used by the Germans, especially the gas known as mustard gas or "ypérite" (so named because it was used for the first time at Ypres), a bathing and cleansing service has been organized by the Service de Santé militaire. It has been discovered that if the victims of these vesicating gases, like "ypérite," are given a bath and proper care within three hours after exposure to the gas, complications will not, as a rule, occur.

Each section for the disinfection of clothing and the douching of the gassed is mobile. It consists of a motor lorry or truck and a trailer. The truck transports the tent, the douche or bath apparatus, floor boards and other necessary accessories. The trailer carries a stove to disinfect the clothing. The whole outfit can be set up very quickly, and it operates in a very simple manner. The men undress in a part of the tent, separate from the bathing outfit. Their clothing is placed in the disinfecting apparatus while they are bathing, and on leaving they receive their clothing which has been freed of every trace of "ypérite." Forty men at a time can be douched; one hundred can be taken care of in an hour by one outfit. The Service de Santé intends to supply each division with one of these outfits.

There has also been organized a special clinic for the treatment of gas victims. This clinic is installed in the school of commerce (hôpital auxiliaire 101 de l'Union des Femmes de France), and is under the scientific direction of Dr. Ch. Achard, professor of pathology and general therapeutics in the Medical Faculty of Paris. This is at the same time a hospital where the gassed are given treatment and where army physicians are instructed in the methods of treatment applicable to these cases of gas poisoning. A research laboratory is attached to the hospital.

Mumps

At a recent session of the Académie de Médecine, Dr. Capitan read a very interesting paper based on his observation of 700 cases of mumps treated in his contagious disease service at the Hôpital militaire Bégin since the beginning of the war. Capitan directed special attention to a new sign, one which he has never failed to find, namely, a very distinct enlargement of the spleen appearing with the onset of the disease and disappearing at its termination. He has also seen in some cases a generally distributed reddish eruption which disappeared in the course of convalescence. Sometimes, though rarely, symptoms are present of irritation of the meninges at the base of the brain; they are not severe and disappear after eight or ten days. Capitan has observed one case of severe cerebrospinal meningitis as a sequel of mumps, but it terminated in recovery.

The Clinical Thermometer

A law has been passed which provides that after nine months no clinical thermometers can be delivered, placed on sale or sold without having first been subjected to verification. Each instrument must bear the name of its manufacturer and after verification it should be suitably stamped, bearing also the date of inspection. Infringements of this law will be punished in the same manner as the use of false weights or measures (a fine of from 11 to 15 francs); furthermore, the instrument will be seized and confiscated. Repetition of the offense will incur a fine of from 50 to 100 francs. In case of false branding, the culprit will be punished by imprisonment of from six months to five years.

Repatriation of Interned Persons

Word has been received from Geneva that the repatriation of the French interned, which has been interrupted for several weeks because of an epidemic of grip prevalent in Switzerland, will be resumed in the usual manner.

Evacuation of the Wounded by Waterways

On account of the difficulty of transportation of the wounded from certain sectors by hospital trains, the Service de Santé militaire has for some time been considering the establishment of a waterways transport for the evacuation of the wounded. However, no definite steps were taken to establish this transport without due consideration of all factors involved. During the recent battles more than 4,000 wounded were transported by water under the best conditions. Orders were issued to make a study of the waterways available for transport between the Oise, the Aisne and the Marne, and to provide the boats needed for such service. The wounded were far more comfortable in the boats than in the trains, which more than compensated for the longer time required to evacuate them. It is necessary, however, to equip the boats in such a manner that operations may be performed as is now done in the ambulances.

Deaths

Capt. George Shrader Mathers, M. C., U. S. Army, Chicago; Rush Medical College, 1913; a son of Dr. William R. Mathers, Prosper, Texas; a Fellow of the American Medical Association; died in Baltimore, October 5, of pneumonia; aged 31. Captain Mathers was a member of the staff of the John McCormick Institute for Infectious Diseases where he had done notable work in isolating the streptococcus in the nervous system in poliomyelitis, in studying the streptococci involved in acute epidemic respiratory infections in man and in studying a remarkable streptococcus epidemic in horses; also in an extensive study of meningitis in one of the military establishments. He entered the service as a lieutenant in March, 1918, and was stationed at Washington, D. C., at Newport News, Va., and finally as director of the laboratory in the base hospital at Camp Meade, Md. It was while working on material in connection with the present epidemic of influenza and the secondary pneumonia that Captain Mathers became a victim of the disease.

Died in the Service

Capt. George S. Mathers, M. C., U. S. Army, 1887-1918

Capt. Charles Henry Gallagher, M. C., U. S. Army, Ithaca, N. Y.; University of Syracuse, N. Y., 1896; aged 42; a Fellow of the American Medical Association; a specialist in anesthesia; whose military service commenced with a tour of duty at Fort Oglethorpe, Ga., when he was ordered to a replacement battalion at Allentown, Pa., and sailed to England, and then to France, where he was a member of the staff of Base Hospital No. 202, Orleans, France; died in that institution, August 28, from bronchial pneumonia.

Wilbur Alson Hendryx, New York City; Rush Medical College, 1874; aged 69; formerly a practitioner of Grand Rapids, Mich., and lieutenant-colonel in the Michigan National Guard; donor of a bacteriologic laboratory to the Medical College of Southern California, Los Angeles; more recently interested in mining; said to have been the inventor of the cyanid process of separating metal from ore, and of many types of mining machinery now in general use; died suddenly in Allentown, Pa., September 21.

Capt. Rae Wyant Whidden, M. R. C., U. S. Army, New York City; Harvard Medical School, 1911; aged 33; a Fellow of the American Medical Association and New York Academy of Medicine; a specialist in diseases of the lungs; visiting physician to Bellevue Hospital, assistant physician at the Presbyterian Hospital Dispensary and assistant surgeon to the Manhattan Eye, Ear and Throat Hospital; died at the Massachusetts General Hospital, Boston, September 25, from pneumonia, following influenza.

Col. Charles E. Doerr, M. C., U. S. Army; Medical College of Ohio, Cincinnati, 1906; aged 35; a Fellow of the American Medical Association; commandant of the Base Hospital at Camp A. A. Humphreys, Accotink, Va.; who entered the Medical Reserve Corps in 1908; was made first lieutenant, Medical Corps, in 1909, and promoted to captain, Medical Corps, in 1912; died at Camp Humphreys, October 3, from pneumonia, following influenza.

Uriah Newton Mellette, Bellingham, Wash.; Eclectic College of Medicine and Surgery, Cincinnati, 1858; aged 83; at one time a member of the Oklahoma State Medical Association; formerly a member of the Florida State Board of Health, and a member of the Oklahoma State Board of Pharmacy; was killed accidentally by a train in one of the tunnels of the Great Northern Railway, near Bellingham, September 22.

Lieut. John Lee Fisher, Assistant Surgeon, U. S. Navy, Wilmington, Del.; Hahnemann Medical College, Philadelphia, 1912; aged 30; a Fellow of the American Medical Association; who entered the naval service, Nov. 17, 1917, and was assigned to duty on the U. S. S. Kearsarge; died, September 24, in the U. S. Naval Hospital, Chelsea, Mass., from influenza.

Thomas William Kohr, Robertsdale, Hammond, Ind.; New York University, New York City, 1884; aged 75; a member of the Indiana State Medical Association; secretary and president of the board of health of Hammond from 1902 to 1905; proprietor of the Robertsdale Pharmacy; died at his home, September 20, from cerebral hemorrhage.

Lieut. Walter Irenaeus Ryder, U. S. N. R. F., Newton, Mass., and Boston; Tufts College Medical School, Boston, 1913; aged 29; a Fellow of the American Medical Association; stationed at the U. S. Navy Radio School, Harvard; died at his home in Newton, September 24, from bronchopneumonia, following influenza.

Capt. Cecil Goodard Morehouse, M. R. C., U. S. Army, Waukon, Iowa; State University of Iowa, College of Homeopathic Medicine, Iowa City, 1913; aged 30; a member of the Iowa State Medical Society; who had been on duty on the Western Front in France, is reported to have been killed in action, recently.

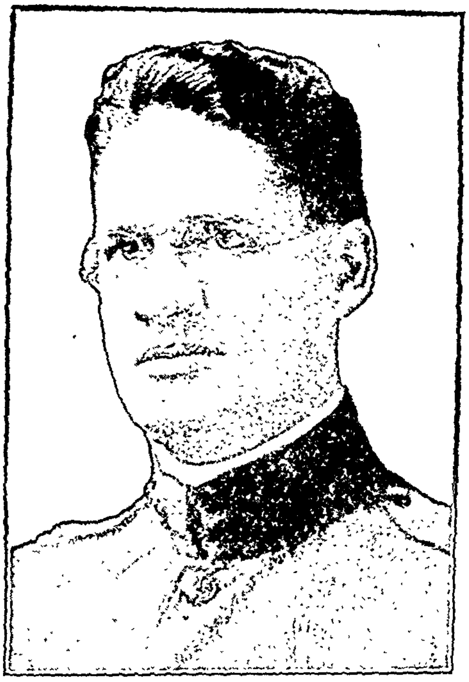
Lieut. Edward James Ware, M. R. C., U. S. Army, New York City; College of Physicians and Surgeons in the City of New York, 1885; aged 59; a Fellow of the American Medical Association and New York Academy of Medicine; visiting surgeon to the Bloomingdale Clinic; died at his home, September 30.

Carrie A. Frost, Almond, Wis.; Northwestern University, Womens' Medical School, Chicago, 1898; aged 53; a Fellow of the American Medical Association; for many years attending physician to the Home for Incurables, Chippewa Falls, Wis.; died at her home, September 22, from tuberculosis.

James Morgan Hurley, San Bernardino, Calif.; Cincinnati College of Medicine and Surgery, 1865; aged 75; at one time a Fellow of the American Medical Association; assistant surgeon, U. S. Army, during the Civil War; for several years health officer of San Bernardino; died at his home, September 25.

Marland Cooper Eaton, Beverly, Mass.; Tufts College Medical School, Boston, 1906; aged 33; formerly a member of the Massachusetts Medical Society; at one time a member of the board of health of Wenham; died at his home, recently, from pneumonia, following influenza.

Butler Presson, Seattle; aged 87; at one time a member of the Grant County (Ind.) Medical Society; a pioneer practitioner and clergyman of the state of Washington; a veteran of the Civil War; died at the home of his daughter in Seattle, August 12, from senile debility.



Died in the Service
IN FRANCE

Major William B. Hudson, M. C., U. S. Army, 1870-1918

(See The Journal, last week, p. 1157)

Lieut. Gilbert Mord Newburger, U. S. N. R. F., Philadelphia; Medico-Chirurgical College of Philadelphia, 1905; aged 38; a Fellow of the American Medical Association; on duty at the Philadelphia Naval Hospital; died in that institution, September 27, from pneumonia.

William B. Bullard, Los Angeles; Bowdoin Medical School, Brunswick and Portland, Me., 1859; aged 89; at one time a

Fellow of the American Medical Association; a member of the Medical Society of the State of California; died at his home, September 23.

Emory J. Walker, New Haven, Conn.; Hahnemann Medical College, Chicago, 1868; aged 73; one of the founders of Grace Hospital, a charter member of its board and secretary of the institution since 1889; died at the home of his son in New Haven, September 9.

George William Yeaton, Milford, Mass.; Dartmouth Medical School, Hanover, N. H., 1902; aged 40; at one time a Fellow of the American Medical Association; a member of the Massachusetts Medical Society; died at his home, September 27, from influenza.

Phillip Townsend Buckley, Boston; Harvard Medical School, 1884; aged 58; a member of the Massachusetts Medical Society; died at his home, September 19, from pneumonia, following influenza.

Abraham P. Williard, Kirksville, Mo.; University of Maryland, Baltimore, 1850; aged 92; surgeon of U. S. Volunteers during the Civil War; died at his home, September 11, from arteriosclerosis.

Francis Joseph Colgan, Colorado Springs, Colo.; L.R.C.P. (Ireland), L.R.C.S. (Ireland), 1910; aged 32; died at a sanatorium in Colorado Springs, September 11, from pulmonary tuberculosis.

Herbert Abraham Hands, Cambridge, Mass.; College of Physicians and Surgeons, Boston, 1882; aged 66; died suddenly in Somerville, Mass., September 18, from heart disease.

Henry C. Carpenter, Lake Odessa and Howard City, Mich.; Homeopathic Hospital College, Cleveland, 1868; aged 82; died at farm home, near Howard City, September 13.

Francis Winfield Sapp, Columbus, Ohio; College of Physicians and Surgeons, Baltimore, 1882; aged 64; died at his home, September 20, from arteriosclerosis.

Whitfield Tillison, Eloise, Mich., formerly of Detroit (license, Michigan, years of practice, 1900); aged 80; died in the county house, Eloise, September 3.

S. Dawson Good, Ashtabula, Ohio; University of Wooster, Cleveland, 1892; aged 50; died at the home of his father in Ashtabula, September 15, from nephritis.

James Leander Forsythe, Lewistown, Ohio; Cincinnati College of Medicine and Surgery, 1875; aged 69; died at his home, September 14, from paresis.

C. W. Knickerbocker, Cedar Falls, Iowa; Hahnemann Medical College, Chicago, 1882; aged 60; died in Chicago, September 14, from heart disease.

Edward J. Buckley, Oak Park, Ill.; Rush Medical College, 1904; aged 40; died at the home of his parents in Lombard, Ill., September 24.

Marc Aurele Trudeau, Lowell, Mass.; University of Vermont, Burlington, 1899; died at the home of his brother in Canada, September 7.

William M. Safley, Townsend, Mont.; College of Physicians and Surgeons, Chicago, 1885; aged 60; died at his home, September 5.

N. A. McCoy, Jackson, Tenn.; Memphis (Tenn.) Medical College, 1855; aged 86; died at his home, September 9.

Josiah B. Custer, Bismarck, Ark. (license, Arkansas, 1903); aged 56; died at his home, September 17.

Marriages

Capt. Charles Watkins Brown, M. C., U. S. Army, Nashville, Tenn., on duty at Vancouver Barracks, Wash., to Miss Anna Murphey of San Diego, Calif., at Portland, Ore., September 10.

Lieut. Michael Francis McGuire, M. R. C., U. S. Army, Chicago, to Miss Rhea F. Ferrin of Jamestown, N. Y., September 25.

Lieut. Ralph Averill Gowdy, U. S. N. R. F., Minneapolis, to Miss Vera M. Unumb at Alexandria, Minn., September 16.

Henry Augustus Peters, Oconomowoc, Wis., to Miss Emma Nicolaus of Fort Atkinson, Wis., September 17.

George Girdwood Pearce, New Bedford, Mass., to Miss Elsie Bruce Jenney of Hyde Park, Boston, recently.

Glen Godfrey Gordon, Baker City, Ore., to Miss Josephine Beaudoin of Joseph, Ore., September 7.

Correspondence

FRIENDLY SOCIETIES AND THE AUSTRALIAN PROFESSION

To the Editor:—I have been directed to inform you of the dispute that has been in existence for some months between the Friendly Societies of Victoria and the British Medical Association.

The lodge doctors have been paid for the past forty years on an average as little as 14s. per annum for the town; this includes attendance on the member and his family and works out at four persons for each member; for the country the average is 16s. per annum per member for the lodge doctor.

For a considerable period of time we held negotiations with the associated lodges called the "Friendly Societies Association" with a view to having the rate of remuneration increased. As the Friendly Societies refused our demands, 100 per cent. of the town members and 96 per cent. of the country members of the British Medical Association on the 31st of last October gave three months' notice of their intention to resign their appointments on the 31st of January of this year and asked for reappointment on the terms of a model lodge agreement that had been drawn up. The Friendly Societies Association refused our terms and established institutes at which the institute doctor was asked to attend from 3,000 to 5,000 patients. The government of the day was asked by the Friendly Societies to take a hand in settling the dispute. The commissioner found that the terms asked for by the British Medical Association were just and equitable. Both sides expressed their willingness to accept the finding of the Royal Commission; but the British Medical Association made it a condition that the institute which had been established should be abolished. They were unwilling to see their men sacrificed for their loyalty to the association in that they had tendered their resignations and were to be left without any means of livelihood should the commissioner's findings be accepted unconditionally.

The lodges are endeavoring to extend their institutes, but find a difficulty in procuring medical practitioners. One of our most bitter opponents, the late president of the Friendly Societies Association, Mr. Samuel Mauger, is now on his way to Canada; and it was stated in Parliament that he purposes securing 1,000 medical officers from America to fill the positions of lodge medical officers vacated by the members of the British Medical Association in what was termed by the commissioner to be "a just demand." The institute doctors are ostracized by other members of the medical profession and are not met in consultation.

My council would esteem it a favor if you would put a "warning notice" in The Journal advising any medical practitioners in your country who might think of applying for any of the positions which might be advertised in your daily newspapers that they should first of all apply for information. By so doing you would be conferring a great favor on our association.

C. Stanton Crouch, Secretary,
Victoria, Melbourne, Australia.

ANESTHETISTS AND ANESTHETIC TECHNICIANS

To the Editor:—A gradually increasing misconception of the art of anesthesia has led to a rather unique condition of affairs.

We find that nurses and other lay persons may, by the simple acquisition of a few rules, become anesthetists. Large institutions have adopted the nurse anesthetist on grounds of economy, expediency and even sentimentality. It is argued that these workers can be employed at little expense, that the supply meets the demand, and that the feminine element eliminates fear and works for smoothness during the induction of the anesthesia.

These institutions may employ lay persons to take their roentgenograms and to make urinary, blood or sputum examinations, but does any one dream of speaking of these workers as the hospital roentgenologist or the attending pathologist? They are employed as technicians. The nurse who administers an anesthetic is an anesthetic technician. She can never be more without a medical degree, for in order to understand the language of anesthesia one must have intimate acquaintance with anatomy, physiology, medicine, surgery, diagnosis, psychology and special branches.

The nurse who in discussion with a medical man attempts to defend a theory relating to anesthesia cannot fail to feel the presumption of it and, if graced with wit, to see the absurdity of such a position. Yet it has actually come to pass that medical men have suffered themselves to be instructed by a nurse in the theory and practice of anesthesia.

In justice to an important branch of surgery and to our medical confrères who devote their training and their energy to its development, let us drop the term "anesthetist" as applied to its nonmedical workers and adopt the term "anesthetic technician."

Paluel J. Flagg, M.D., New York.

A PHYSICIAN'S FINANCES

To the Editor:—I do not believe that advertising in a daily newspaper and in the physician's waiting room, and the sale to the highest bidder of his unpaid accounts, as advocated by physicians and noted under "Editorial Comments" in the September issue of the *Journal of the Michigan State Medical Society*, is the proper remedy for people who do not pay their physician. A more radical one is needed. Since the physician must consummate one of the great fundamental instincts of human life, that of self-preservation, or making a living, why not strike at the root of the evil, calling a spade a spade, and not beat around the bush? The health of the physician, which is his greatest asset, suffers by the fatigue of long hours in trying to conserve human life. He responds to the public's call the entire twenty-four hours of the day, while even the common laborer has the law's protection to work no more than eight—the physician being the only worker who wears himself out for people who do not pay.

A political board or the claim adjuster of an insurance company should not be permitted to fix a doctor's fee. The individual who fails to pay his physician a small fee for saving his life will pay a lawyer thousands of dollars to be saved from the penitentiary.

To keep himself efficient the physician requires both money and recreation; hence he should take the honest, fearless course, demanding spot cash payment or giving no service. Those who declare this remedy too harsh or drastic should remember that the physician has suffered long from the moth-eaten abuse, and because patients will not protect him he must protect himself unless he wants to qualify as a medical missionary. The public can profitably have a law enacted that will be a protection in case of illness not only against the overworked general medical practitioner, but also against the weary medical specialist who employs inexperienced assistants to care for his great swarm of patients—this law to limit the amount of work the physician undertakes, because beyond a certain point, as his practice increases, his efficiency to the ill diminishes.

I am of the opinion that, eventually, in the interest of both physician and patient, the state will not only graduate the physician but will support him after graduation with a just compensation—one that will be great enough to guarantee him, not only a living, but also professional necessities for which, under the present system, it is his lot to struggle.

I have been in the general practice of medicine since 1890 on the site of my birthplace in Detroit, treating patients from all sections and classes of the city. For the twenty years ending Dec. 31, 1909, during which time I treated every ill patient that applied, only 2 per cent. paid promptly, and 60 per cent. failed to pay me anything. Profiting by this experience, on Jan. 1, 1910, I adopted my present rule, to ask every new patient before he receives service if he can pay my fee. If his reply is negative he is told that I carry no accounts with strangers and that he must seek treatment from the Detroit Public Welfare Commission free medical clinics and dispensaries, or elsewhere. For the eight and a half years ending June 30, 1918, of my total number of new patients, 47 per cent. were refused treatment, the balance paying cash and obtaining my services. Expenses dropped with diminished business, leaving my average net income per month for this period 276 per cent. more than my average net returns per month for the preceding twenty years, although it was an amount not more than that earned by the average Detroit salaried layman. The rule gives me more time for refreshment, reading and sleep—all needed to make for physical and mental efficiency in serving such of the ill as apply who are willing to pay promptly. I need not say that dead beats, deliberate grafters and delinquents make a rigorous howl against my business methods, although I treat all applicants known to be honest indigents free of charge.

Because of my experience of nearly thirty years, I recommend to physicians who have not medical missionary ambition, instead of the "schemes" above mentioned and pending the time when they will be paid out of the annual public tax budget, that they do a strictly cash business with patients whose credit is not known to be first class—the honest indigents alone excepted—and to require those with such good credit to keep their accounts paid up at least every thirty days.

John Linn Irwin, M.D., Detroit.

ENTEROCOLOSTOMY FOR ACUTE OBSTRUCTION OF THE TERMINAL ILEUM FROM INFECTION IN THE PELVIS AND LOWER ABDOMEN

To the Editor:—In his article in The Journal, Sept. 7, 1918, Dr. B. M. Anspach recommends an enterocolostomy for acute obstruction of the terminal ileum caused by infection in the pelvis, and cites clinical results. I am heartily in accord with his report and wish to emphasize my opinion by citing an article I wrote in the *Boston Medical and Surgical Journal* (1913, **169**, 313) in which I advocated this identical procedure for just such obstructions and reported three successful cases. Since then I have had four more, one in a child aged 4 years, all successful. I had operated on my first three patients previous to an article by Cheever (*Boston Medical and Surgical Journal* (1913, **168**, 719) in which he first described this type of obstruction of the terminal ileum from suppuration in the pelvis, the condition in his cases and mine being due to the appendix. He advocated enterostomy, which proved fatal in two out of three cases reported.

W. Sampson Handley (*British Journal of Surgery*, 1915, **3**, 157) reports a similar condition, in addition a portion of the pelvic colon being obstructed by this inflammatory exudate, two areas of the intestine involved, to which he aptly applies the term "ileus duplex." He advocated ileocolostomy if the anastomosis could be performed below the area obstructed, and if that was impossible, to perform an ileocolostomy above the obstruction in the colon and in addition a cecostomy to drain the contents of the colon and ileum.

A colostomy or enterostomy for an obstruction is often a life-saving procedure and no doubt is not performed frequently enough; but when an anastomosis of the obstructed intestine to a point low in the colon, where absorption is nil, can be performed, with results equally as good, it is to be advocated in preference to drainage to the surface, which not only is an additional care but requires a second operation for its closure.

Dr. Anspach's report is interesting and confirms a procedure which I believe I was the first to report in August, 1913.

C. A. Roeder, M.D., Omaha.

Dispensary as a Social Agent.—The province of the dispensary is extending far beyond the clinic walls, until it now reaches out into the community as a public agent. This is the need which has brought about a readjustment by the injection into the operation of dispensaries social service principles and public welfare interests.—Lucy C. Catlin, The Hospital as a Social Agent in the Community.

Book Notices

Nerve Wounds: Symptomatology of Peripheral Nerve Lesions Caused by War Wounds. By J. Tinel, Preface by Professor J. Dejerine. Authorized Translation by Fred Rothwell, B.A.; Revised and Edited by Cecil A. Joll, M.B., M.S., B.Sc. Senior Surgeon Richmond Military Hospital, Cloth. Price, $4.50. Pp. 317, with 323 illustrations. New York: William Wood & Co., 1917.

This work has been prompted by the great number of nerve wounds produced by war injuries. There were 639 cases which formed the basis of this study, and of these, 408 involved the upper and 231 the lower extremities. A brief synopsis on the character of the injuries, the changes that take place in the nerve, degeneration and regeneration, and the formation of neuromas and pseudoneuromas forms the opening part of the first chapter. The general subject is then subdivided into four parts. Part 1 is devoted to a general survey, and consists of five chapters, on nerve lesions in war wounds, clinical examination of a nerve, electrical examination, clinical types, and general diagnosis of peripheral nerve lesions. Part 2 deals with the nerves of the upper limb and Part 3 with those of the lower limb. Part 4 presents the conclusions, some of which are interesting and may be mentioned:

> We are justified in affirming that the prognosis of peripheral nerve lesions is, on the whole, favorable.
>
> Every peripheral nerve affected by traumatism tends to regenerate.
>
> Widespread destruction of peripheral nerves is also repairable by nerve grafting.
>
> Nerve suture practiced under favorable condition almost invariably succeeds.
>
> Early intervention does not appear to be an indispensable condition; we have witnessed the success of nerve sutures practiced thirteen and fifteen months after the wound.

The author, by reason of his large experience in war injuries, has been able to present in this work a valuable contribution to our knowledge of traumatic nerve lesions.

Fibroids and Allied Tumours (Myoma and Adenomyoma): Their Pathology, Clinical Features and Surgical Treatment. By Cuthbert Lockyer, M.D., B.S., F.R.C.P., Vice-President Obstetrical and Gynaecological Section, Royal Society of Medicine. With an Introductory Notice by Alban Doran, F.R.C.S., Consulting Surgeon to the Samaritan Free Hospital for Women. Cloth. Price, $25. Pp. 603, with 316 illustrations. New York: The Macmillan Company, 1918.

Dr. Lockyer has had an extensive experience, both as a clinician and as a gynecologic pathologist, during many years of work in the Samaritan Hospital, London. This volume embodies his own observations, as well as those of many other prominent workers, and may be regarded as the latest and most important work that has been written on the subject. The book consists of three parts, considering, respectively, myoma, adenomyoma and operative measures. It is illustrated in the most comprehensive manner, and both text and drawings are highly creditable to the publishers; indeed, it is one of the finest medical publications that has been produced in Great Britain in recent years.

An elaborate analysis of the work is not possible within the limits of a review article. It is a great storehouse of observations, theoretical considerations occupying but a small portion of the contents. In Part I, on secondary changes in myoma, full consideration is given to malignant complications, the author having no doubt as to the possibility of malignant transformation of the myoma cell. He points out that while sarcomas of connective tissue origin are either spindle-cell or round-cell those of muscular origin are invariably spindle-cell. Regarding hyaline degeneration, he states that this condition is often a precursor of or intimately connected with sarcomatous change. The rarity of tubal gestation in myoma uteri is emphasized, and the fullest consideration is given to the association of uterine pregnancy and myoma. Most opportune is the section dealing with radiotherapeutics. This is a valuable summary of extensive observations from various sources regarding treatment by the roentgen ray, radium and mesothorium. Lockyer believes that radiotherapy acts chiefly by destroying the ovaries, but that the roentgen ray has also a direct influence on the myoma cells, though this is variable in producing atrophic changes and shrinkage. Indeed, he is skeptical as to the ability of the roentgen ray to cause permanent atrophy in myoma. Radium and mesothorium used alone are not so suitable as the roentgeon ray, as no shrinkage of the growth can be expected. Radiotherapy should be employed only when the myoma is not complicated by adhesions, degeneration and other new growth. The contraindications outweigh the indications for radiotherapy.

Part II, dealing with adenomyoma, is a masterly review of our knowledge of this growth, and can be recommended as a valuable work of reference. The etiologic analysis gives full consideration to the wolffian origin hypothesis of von Recklinghausen, the mucous membrane origin so strongly urged by Cullen, the inflammatory theory of mucosal invasion, the embryonic or congenital theory, and the serosal theory. Lockyer believes that heterotopy of serosal epithelium is the probable explanation of the existence of epithelial spaces and cysts in most of the extra-uterine swellings found between the rectum and the genital tract. There is also a detailed description of these tumors as found in the fallopian tubes, round ligaments, ovarian ligaments, broad ligaments, rectogenital space and alimentary tract. The author is of the opinion that adenomyomas very rarely become malignant. They are more frequently associated with pelvic peritonitis than myomas. Radiotherapy is unavailing in the treatment of these tumors, and may excite inflammatory processes.

Part III, dealing with surgical measures and with postoperative complications, is written in a manner that gives evidence of a wide and sound clinical experience.

The author and publishers of this important volume are to be highly congratulated on its production. It should find a place in every medical library in America.

Local and Regional Anesthesia, with Chapters on Spinal, Epidural, Paravertebral, and Parasacral Analgesia, and on Other Applications of Local and Regional Anesthesia to the Surgery of the Eye, Ear, Nose and Throat, and to Dental Practice. By Carroll W. Allen, M.D., Assistant Professor of Clinical Surgery at the Tulane University of Louisiana. With an Introduction by Rudolph Matas, M.D., Professor of General and Clinical Surgery at the Tulane University of Louisiana. Second edition. Cloth. Price, $6.50 net. Pp. 674, with 260 illustrations. Philadelphia: W. B. Saunders Company, 1918.

The perusal of this book will prove interesting to any one who is at all concerned with the subject of local anesthesia. From the standpoint of the practical surgeon there is a great deal of valuable material, most of which evidently is presented only after prolonged, careful observation and trial by the author and his associates. There is much that may be given instant approbation; there is also much, particularly in connection with major procedures, that the prudent surgeon might not feel justified in applying unless the indications were of the most urgent nature. It must be admitted that the author is judicially conservative and that in general the discussion is well balanced—there is no overzealous praise of pet procedures. The first eleven chapters deal with the history and theory of local anesthesia, an analysis of fifteen or twenty local anesthetics with a chapter on toxicology, and a thorough presentation of the principles of technic. The remainder of the book consists largely of descriptions of the various operations possible under local anesthesia.

Naval Hygiene. By James Chambers Pryor, A.M., M.D., Medical Inspector, United States Navy. Published with Approval of the Surgeon-General, U. S. Navy and by Permission of the Navy Department. Cloth. Price, $3 net. Pp. 507, with 153 illustrations. Philadelphia: P. Blakiston's Son & Co., 1918.

The author has been in service on board ship and in naval stations, and has taught naval hygiene in the United States Naval Medical School. The book is based on the need for a text of this character as shown by the work of the classes in the United States Naval Medical School. The problems on board ship are different from those of Army camps. Thus the question of air aboard ship and of ventilation assumes far greater relative importance than in military camps. In the same way the question of water supply and sewage disposal aboard ship are special problems. In fact, all of the problems of hygiene and sanitation in the Navy are distinctly special in character. The civilian physician called to active service in the Naval Medical Reserve Force will, therefore, find this textbook of great value. It is well illustrated, quite elementary and very practical.

Medicolegal

Burden of Proof on Party Given Wrong Medicine on Prescription

(Fagan v. McRae (N. Y.), 169 N. Y. Supp. 577)

The Supreme Court of New York, Appellate Term, First Department, reverses a judgment for $500 that was rendered in favor of the plaintiff, and orders a new trial, on the ground that the plaintiff failed to sustain the burden of proof in this action against a druggist who was charged with having failed to fill a prescription given by the plaintiff's physician according to its directions. The court says that the defendant admitted the filling of the prescription, but denied that it was incorrectly filled. The medicine was prepared and delivered by the defendant on Tuesday. The plaintiff was given the medicine every three hours. On Thursday the physician called, and the plaintiff had by that time taken two thirds of the contents of the bottle. She had become very sick on Tuesday night, and had grown worse. The physician was shown the bottle on Thursday, and found the contents to be of whitish color, with much sediment. The medicine prescribed was of a clear brownish color. After that the plaintiff took no more of the wrong medicine. She continued ill, and was treated by the physician for three months. The defendant offered no evidence. The proof that the defendant had delivered a medicine different from the one ordered by the physician seemed to be adequate. The court was thus called on to determine what injury, if any, was caused by the error. Although the plaintiff was ill for three months, it nowhere appeared in the record what her ailment was at any time; in fact, it did not appear that the physician himself knew. All the court had were vague suggestions that the plaintiff might have been suffering from so-called German measles. The only evidence from which any inference might be drawn as to the effect of the wrong medicine was the physician's testimony that the plaintiff's condition was made worse; that the medicine certainly was bad for the plaintiff. The witness, being unacquainted with the ingredients of the medicine, could have had no reason for his conclusion, other than the circumstance that a different medicine was given. The fact that the plaintiff grew worse might, for all that appeared, have simply been due to the failure of the patient to receive the benefit of the remedy prescribed. The burden was on the plaintiff to show that the result of the wrongful act of the defendant—the giving of the wrong medicine—was the proximate cause of the injury claimed to have been suffered. The plaintiff failed to sustain the burden.

Liability of Lessors for Death from Failure to Heat Premises

(Keiper v. Anderson et al. (Minn.), 165 N. W. R. 237)

The Supreme Court of Minnesota affirms an order overruling a demurrer and holds that an action was maintainable that was brought by a woman as administratrix to recover damages for the death of her husband alleged to have been caused by the wrongful acts or omissions of the defendants in failing properly to heat a store building which they had leased to her husband and contracted to keep heated to a comfortable and proper temperature. The complaint stated the terms of the contract and alleged negligence and carelessness on the part of the defendants in failing properly to attend to the heating as the cause of Mr. Keiper's death. The defendants demurred, contending that the action could not be maintained because it was on contract, and because the statutory action to recover for death by wrongful act or omission could be maintained only when the cause of action was in tort. The court says that it is doubtless true that the word "tort," as well as the word "wrongful," usually signifies a breach of legal duty, independent of contract rights. But this is by no means always true. Take such contract relations as carrier and passenger, physician and patient, attorney and client, landlord and tenant; when there is actual negligence or wrong on the part of the carrier, physician, attorney or landlord, is it not still negligence or a wrong notwithstanding that the duty is imposed by the contract? There may be a breach of contract without negligence, but there may be negligence or wrongful acts or omissions in the performance of a contract. It seems to the court to make no difference whether the duty to use due care is one imposed directly by law or exists because of the contract relation of the parties. The court is unable to see why the complaint in this case did not allege negligence on the part of the defendants and that Keiper's death was caused by their wrongful acts and omissions.

COLORADO STATE MEDICAL SOCIETY

Forty-Eighth Annual Meeting, held at Estes Park, Sept. 9-11, 1918

The President, DR. EDWARD JACKSON, *Denver, in the Chair*

Operations for Gastric and Duodenal Ulcer

DR. A. R. POLLOCK, Monte Vista: The surgical methods of treating stomach and duodenal ulcer are: 1. Gastro-enterostomy. 2. Direct attack of the ulcer, with or without gastro-enterostomy. 3. Pyloric closure with gastro-enterostomy, with or without direct attack of ulcer. 4. Gastroduodenostomy. 5. Resection of stomach, gastro-intestinal continuity reestablished by (*a*) anastomosing proximal and distal ends as is done in sleeve resection; (*b*) by the second method of Billroth as is done after pylorectomy; (*c*) by gastrojejunostomy, the Polya operation, following extensive resection of stomach, or by (*d*), antecolic gastrojejunostomy, as described by Balfour. The operation should be adapted to the case.

DISCUSSION

DR. C. B. LYMAN, Denver: There is a great difference of opinion among surgeons as to what procedure should be carried out in different cases. Gastro-enterostomy is done more frequently than any other operation, but it is not a perfect procedure. Patients return with various symptoms. The right method may not have been used. The operation is done as a mechanical one and must be done right. The opening between the jejunum and stomach may have been made so close to the pylorus that there was no drainage, or the opening may be too small. The gastro-enterostomy opening must be made much larger at the time of operation than seems necessary so as to provide for future contraction.

DR. C. D. SPIVAK, Denver: Surgeons are beginning to realize that operations for ulcer of the stomach, no matter what method is used, are not always successful. The patient is not cured.

DR. FROST C. BUCHTEL, Denver: The essayist leads us to believe that we must exercise a certain amount of judgment in the selection of the operation, depending on the type of ulcer. Gastro-enterostomy cures a very large percentage of cases of peptic ulcer after they have had half a dozen so-called medical cures. Many of the cases of peptic ulcer are duodenal ulcers, and gastro-enterostomy is the best type of operation for duodenal ulcer. Some of our bad results from gastro-enterostomy come from the fact that we expect the operation to cure gastric ulcer, which it does not do. I think that surgeons are now agreed that direct attack of the ulcer, usually with some form of drainage operation, is desirable in gastric ulcers.

DR. A. R. POLLOCK, Monte Vista: Chronic ulcer is a surgical condition. It is true that some patients are not relieved by gastro-enterostomy, but gastro-enterostomy in itself is not sufficient. Something more should be done.

The Contributions of Colorado Physicians to Medical Literature, and The Journal of the American Medical Association as the Index

Dr. C. D. Spivak, Denver: Medical literature comprises the following classes: 1. Literature of all the branches of medical sciences as taught in all the medical schools, including those usually called irregular. 2. Literature of all other sciences and arts so far as they are applied to and have a bearing on the medical sciences. 3. Biographies of medical men and of scientists who have contributed to the advancement of medicine. 4. History of medicine. 5. The writings of medical men outside of medical science in which the influence of their medical training may be discerned. 6. General literature which has a specific bearing on or reference to medicine and physicians. About 1900 The Journal of the American Medical Association introduced new forms, new type, new departments. The number of readers increased, the number of advertisers multiplied. The Journal became a prosperous concern, a big business. Nothing succeeds like success. Those who scorned the idea of having their name associated with the plebeian periodical published in the wild and woolly West sat up and took notice, and then flocked to The Journal with their contributions. For who is so blind as not to see that a periodical, the circulation of which is rapidly nearing the 100,000 circulation mark, is a better medium than that of any medical publication in this country, the circulation of the best of which never exceeded 25,000 copies?

Dermatitis Seborrhoeica

Dr. G. P. Lingenfelter, Denver: No treatment will be successful unless it is thoroughly recognized that the scalp is the important factor in connection with the general disease. It is an excellent plan to remove the oil and the greasy plugs by means of deodorized benzin before applying the remedies. This is a most satisfactory and effective cleansing agent, and is much less irritating to the skin than ether. Lesions on the face are best treated by means of lotions, and for this purpose the lotio alba, with a small amount of sulphur added, serves admirably.

An excellent combination is: ammoniated mercury, 1.3 gm.; liquor carbonis detergens, 4 gm.; petrolatum, 3 gm. A paste is made and applied several times a day to the dry scaling patches frequently seen at the border of the scalp.

The thickened epidermal patches (seborrheic warts) of middle aged or elderly persons can be removed by the use of keratolytic remedies, such as salicylic acid, or by repeated exposures of the roentgen ray, by the curet, or by the application of carbon dioxid snow. The latter remedy nearly always gives satisfactory results from a cosmetic standpoint, and recurrences have been very infrequent. It is much safer and speedier than the roentgen ray, and because of the freedom from possible undesirable effects is much to be preferred. Recently, as an adjuvant to local treatment, I have had satisfactory results with the Alpine sun lamp, employing sufficient exposure to produce an intense erythema.

Necessary Cooperation in Prenatal Care and Obstetrics

Dr. Foster H. Cary, Denver: Prenatal care should begin as soon after the advent of pregnancy as possible. The public should be educated to the importance of seeking advice soon after conception has occurred. The excellent results following the establishment and intelligent conduct of prenatal clinics have been evident not only in the diminution of avoidable complications at labor, but also in the end-results months postpartum. Many physicians fail to impress on patients the necessity of frequent visits to the office for examination. Prenatal care embraces a careful family and personal history, an early and complete examination, blood pressure readings, a Wassermann test, pelvic measurements, bimanual examination for displacements in the early months before the fundus has risen above the symphysis, urinalysis and detailed instructions as to hygiene, diet, exercise, work and excesses. The social service worker is best adapted to work in prenatal care. Her position makes it easy for her to inspire confidence and to act as a great factor in the establishment of cooperation between the charities and the physicians or hospitals.

Absolute Rest in the Treatment of Pulmonary Tuberculosis

Dr. S. W. Schaefer, Colorado Springs: Tuberculous patients usually come to us below par in body and nervous energy and weary in mind. Rest in bed is one of the chief aids in building up the run-down body; antibodies must be formed to combat the tubercle bacilli. Instead of wasting the small store of energy the patient still has, in holding himself erect or sitting or moving about, all this energy should be concentrated on fighting the disease.

Eversion of Tissue Margins in Wound Approximation

Dr. C. E. Tennant, Denver: The most successful repair of a wound occurs when there is an accurate approximation of the various layers of tissue. Since most of these tissues are of but knife-blade thickness, it stands to reason that cell proliferation will not bridge the gap so well when these narrow margins are barely approximated with the average method of suturing, as when brought side to side by eversion. As a rule, the result of wound healing will be satisfactory in a reverse ratio to the amount of granulation tissue produced or required in the process of repair. This eversion is secured by placing a tenaculum at each angle of the incision in the layer of tissue to be united and put the tissue on the stretch. The layers to be sutured then come well out of the wound, the margins become everted, and with a good strong thumb forceps the operator grasps the everted edge, including both margins, and the needle is engaged in what seems to be one layer of tissue. The ordinary over-and-over suture or lock stitch is used for a short distance. At various intervals along the line a continuous mattress suture is dropped in order to keep the tissues in eversion when they fall back into the wound, and then again the over-and-over suture is applied for a short distance. These two types of suture are used at various intervals until the layer of tissue is completely approximated. The next layer is then sutured in like manner.

Blood Transfusion

Dr. Frost C. Buchtel, Denver: An analysis of the last 100 blood transfusions I have given shows the following results: 46 of the 100 were given for pernicious anemia; 16 for bleeders (purpura hemorrhagica and hemophilia); 14 for acute hemorrhages; 12 for secondary anemia; 11 to prepare patients for operation (9 of this list are also included in other groups); 7 for sepsis; 1 for shock; 1 for malnutrition, and 1 for Hodgkin's disease, making a total of 109, 9 of which were counted twice. The acute hemorrhage cases give brilliant results. The transfusions under this heading were given for the following conditions: 3 for gastric hemorrhage; 3 for postoperative bleeding; 1 for hemorrhage in typhoid fever; 2 for placenta praevia; 1 for premature separation of the placenta; 1 for postpartum hemorrhage; 1 for ruptured ectopic gestation, and 1 for hemorrhage from papilloma of the bladder. Among these fourteen transfusions for acute hemorrhage there were three deaths.

There is a great field for transfusion in preparing patients for operation. Seven of the eleven patients in this group could not have been operated on at all without the transfusion. All the patients stood the operation well.

Tuberculosis in Children

Dr. George Cattermole, Boulder: Recent studies have made it more certain that tuberculosis is contracted chiefly in infancy and childhood. The percentage of children that are infected before the age of 15 years varies according to locality. Between the ages of 4 and 15 years there are not many children who show active tuberculosis. Before 4 years of age, tuberculosis of the bronchial glands, meninges, peritoneum and lungs is common. After 4 years the most common seat is in the bronchial glands, the cervical glands are also often involved, and, in a smaller number of cases, the joints. The mortality from tuberculosis is low between the ages of 4 and 15 years, even though the number of children that react to the skin tests gradually increases during these years. These children have a high degree of resistance to tuberculosis, and it is then that they should acquire immunity. In those children that have active lesions in the joints, glands or peritoneum, there is a marked tendency to heal.

It is very difficult to diagnose tuberculosis in children from physical signs in the chest. The skin tests should be used in order that we may know all of the children that are infected with tuberculosis. I am in favor of a general test of all schoolchildren. It would enable us to study the progress and development of the disease and to determine whether those that are infected in childhood or those who are infected in later life are the ones who make up the army of consumptives.

Tuberculin skin tests were made by me on 419 children. Of these, 47 per cent. showed a positive and 53 per cent. a negative reaction. One hundred and sixty-five patients showed 42 per cent. positive and 58 per cent. negative reactions. Two hundred and fifty-four charity patients showed 50 per cent. each of positive and negative reactions. Of 167 children tested at the university dispensary, 47 per cent. were positive and 53 per cent. negative, even though a large number of these children were from families in which there were one or more cases of tuberculosis. Of eighty-seven children examined at the orphans' home, 57 per cent. gave positive and 43 per cent. negative. This was the highest percentage of positive reactions obtained in any group of children, probably because of the fact that these children came from homes in which one or both parents had died of tuberculosis.

A history of exposure was obtained in 202 cases. Among 101 children that gave a negative reaction, sixty-one had been exposed to tuberculous parents and had escaped infection, while forty had not been exposed to infection in the home. This is a little more evidence of exposure in the home as being the chief cause of tuberculous disease in children.

23. **Epinephrin Vasodilator Mechanisms.**—That sympathetic vasodilators to the limb exist and that they are sensitive to epinephrin at the gangliar and peripheral ends is the conclusion reached by Hartman, and his associates. While a limb is dilating from denervation, epinephrin produces an increase in volume with difficulty, but while the reverse change is taking place the dilator effect of epinephrin begins to reappear. After denervation of a limb, of greater duration, the dilatation from epinephrin occurs from a greater range of doses than is the case in the normal limb. The peripheral action (dilatation) becomes similar in both normal and denervated limbs after perfusion. Under these conditions also dilatation occurs with a greater range of doses. Depressor doses of epinephrin can cause dilatation of a limb by action on the gangliar mechanism. Epinephrin acts on both gangliar and peripheral mechanisms in producing dilatation of the hind limb.

24. **Vascular Response of Epinephrin on Nerve Ganglions.**—The authors found that epinephrin occasionally produces constriction in the hind limb by its action on the sympathetic and dorsal root ganglions. Constriction of the intestine is sometimes produced by epinephrin acting on the superior mesenteric and dorsal root ganglions.

26. **Acapnia and Shock.**—The purpose of this paper is to present facts indicating that, in addition to indirect vasomotor nervous influences, there is a peripheral chemical control of the volume of the venous return, and reasons for holding that it is this chemical control which is the chief factor in the high venous pressure of muscular work and in the lowering of venous pressure induced by acapnia and itself causing the circulatory depression following anesthesia and surgical operation. Two series of experiments were made. The general significance of the results obtained appears to be as follows: Procedures which strongly influence vasomotor innervation, for instance, spinal section, spinal stimulation, stimulation of an afferent nerve, splanchnic stimulation and intravenous injection of epinephrin, cause on the whole decidedly greater alterations of arterial than of venous pressure, and the alterations of venous pressure are often only momentary and therefore largely indirect and secondary to redistribution of blood. In the beheaded cat increase of carbon dioxid in the blood (with ample oxygen), which has little or no effect on arterial pressure other than an increased amplitude of pulse, causes an enormous rise of venous pressure. The pressure develops gradually as the carbon dioxid accumulates in the tissues and falls again gradually as the excess of carbon dioxid is ventilated out of the body.

These facts, and others, indicate the existence of a venopressor mechanism distinct from the vasomotor nervous regulation and consisting in a peripheral chemical control, largely through variations in the carbon dioxid content of the venous blood, over the venous pressure and the volume of the venous return. As venous pressure and the volume of the venous return are essential elements in the diastolic filling of the heart, and thus are factors in determining the volume of blood circulated in unit time, it appears probable that the venopressor mechanism may play a part in the increased circulation during muscular exertion. It thus assists in coordinating the volume of the blood stream with the energy expenditure and gaseous metabolism of the tissues. As it is now generally admitted that in shock it is the decreased venous return which is the cause of the fall of arterial pressure, the relation of carbon dioxid to the venopressor mechanism affords an explanation of the mode by which acapnia induces circulatory failure.

27. **Influence of Drugs on Intestinal Rhythmicity.**—Sets of five segments from different parts of the bowel were studied by Alvarez under identical conditions in a beaker of aerated Locke's solution. Of the seventy-five drugs tested, eight increased the rate, forty-six slowed it and twenty-one had no effect. Calcium chlorid, calcium lactate, benzene, nicotin, ammonia, sodium hydrate, potassium hydrate and mercuric chlorid increased the rate. Marked slowing was produced by alum, antimony potassium tartrate, carbon dioxid, cascara, chloral hydrate, digitalis, ergot, formaldehyd solution, hydrochloric acid, ipecac, jalap, phenylhydrazin, potassium cyanid, quinin salts, senna, and sodium citrate and nitrite. With a number of the drugs the rate of the ileal segment was more affected than that of the duodenal segment; and there was a gradation in the percentage of increase or decrease from one end of the bowel to the other. This suggests that the rate in the upper part of the intestine is more stable and perhaps more nearly maximal than it is in the ileum.

Drugs which increase or decrease the tone and amplitude of contraction do not necessarily affect the rate. Thus, pilocarpin and barium chlorid, which increased the tone, decreased the rate. Calcium salts, which increased the rate, diminished the amplitude of contraction. This suggests two phases of muscular metabolism acted on, one concerned with tone and amplitude, the other with the rate. Digitalis slows the intestinal contractions much as it slows those of the heart. Excepting those cases in which the colonic rhythm was stopped entirely, it was practically unaffected by the drugs which caused marked changes in the rate of the small intestine.

29. **Fat in Alimentary Mucosa of Starved Cats.**—McIntosh claims that normally there is fat in the epithelial cells of the stomach and intestine which is not associated with the phenomenon of fat absorption; that this normal fat varies, however, with some definite cycle of functional activity of the cells themselves; that at certain periods the lipoids are in such a condition that they can be demonstrated by histologic methods while at others they are not demonstrable. The normal presence of these lipoids must be taken into account in estimating experimental results.

30. **Extirpation of Duodenum.**—The experiments here reported indicate that animals can survive indefinitely a complete extirpation of the combined jejunum and ileum. A dog was kept three months after a complete removal of the pyloric part of the stomach, the entire duodenum and the upper jejunum. The mucosa of this region of the digestive tract is not comparable to the suprarenals or parathyroids in function. The normal secretions of the duodenum and jejunum are not toxic. When bacteria are excluded from the lumen of the intestine, various pathologic changes even to complete occlusion of the blood supply to an isolated piece of intestine with resulting autolysis and reabsorption, can take place without the elaboration of sufficient toxic substances in the cells themselves or in their secretions to kill the animal. The duodenum does not excrete in the duodenal juice any substance necessary for life or for the function of the intestine lower down.

31. **Venopressor Mechanism.**—A preparation of the large intestine in the dog is described by Hooker on which a rise of venous pressure may be demonstrated independently of arterial and other factors. The rise of venous pressure may be obtained by (*a*) stimulation of the nerve to the part (peripheral mechanism); (*b*) stimulation of a sensory nerve (central reflex mechanism), and (*c*) central stimulation by asphyxia. Attention is called to the fact that activity of the intestinal muscle may contribute to the movement and pressure of the blood in the portal venous system.

36 Case of Toxic Meningitis Following Measles. F. Tweddell, Summit, N. J.—p. 482.

32. **Parenteral Administration of Fluids.**—Silverman's personal experience with puncture of the longitudinal sinus comprises some twenty cases. Some were done for diagnostic purposes—for obtaining blood for a Wassermann test or for chemical analysis or for blood culture. In the majority of instances, intravenous injections of salt solution, glucose or sodium bicarbonate were given. In no case were any untoward symptoms observed incidental to the injection. Some severe cases of cholera infantum have shown a marked improvement after a single injection of salt solution intravenously. In one case in which the heart had apparently stopped, experience with experimental animals suggested the use of epinephrin, and a suitable dose in normal saline was injected into the sinus with most gratifying results. The accumulated experience of the past three years gives sufficient evidence of the usefulness of this method. It should be remembered that it is used in exceedingly sick babies in whom the prognosis is at best unsatisfactory.

33. **Spinal Fluid in Poliomyelitis.**—Observation made in fifty cases leads Larkin and Cornwall to believe that the increase of the pressure is the most persistent of the changes in the spinal fluid and that it does not disappear until several months after the acute symptoms have subsided. After the tenth day it is present in nearly 100 per cent. of cases. An increase in pressure occurred in 93.5 per cent. of fluids examined from the first to the fifteenth day of illness. It persisted longer than any of the other fluid changes. Of the fluids, 93 per cent. showed an increase in the globulin content. This increase was noted before the pleocytosis and persisted longer. A pleocytosis occurred in 86 per cent. of fluids. The lymphocytes, especially the small variety, predominated. The cells diminished before the globulin. The total leukocytes of the blood were highest during the first ten days, averaging 18,500. As the total leukocytes diminished there was a relative increase in the polymorphonuclears. There was no curve noted with the Lange colloidal gold reaction diagnostic of anterior poliomyelitis. No parallelism existed between the colloidal gold curve and the other spinal fluid or blood findings. There appeared to be a tendency for the height of the colloidal gold curves to increase with the severity of the infection. The higher curves were more frequent from the tenth to the fifteenth day. Of the colloidal gold curves 63 per cent. were humped. Of the five fatalities among forty-nine cases, one fluid gave a curve to two, three fluids gave curves to three, and one fluid gave a curve to four. Three of the fluids from fatal cases were humped or of the syphilitic type, and two were descending, resembling the paretic type.

42 *Communicable Diseases in National Guard and National Army of United States During Six Months from September 29, 1917, to March 29, 1918. V. C. Vaughan and G. T. Palmer, Washington, D. C.—p. 635.

42. **Communicable Diseases in United States Army.**—This report has been prepared with the object of giving publicity during the present year to the salient features of communicable disease incidence in the United States Army during the past winter. The statistical data have been drawn from the telegraphic reports sent in weekly from each camp, cantonment and army post or station. The data given deal for the most part with thirteen National Guard camps and sixteen National Army cantonments, which represent over 70 per cent. of the troops in this country during the period in question.

It was seen that the average death rate (9.1) for the whole army is higher than that of New York (5.5), St. Louis (5.5), Pittsburgh (6.2), Chicago (5.2). The death rates in the different camps show wide variation. In three National Guard camps it was between 23 and 29 per cent.; in three between 10 to 1 per cent.; in two between 8 and 9 per cent.; in five between 2 and 3 per cent. In the National Army camps, the death rate was 30.7 in one camp; between 10 and 20 per cent. in four; between 7 and 9 in three; between 5 and 6 in three; between 3 and 4 in four, and under 3 in one.

The reasons for the wide variations in the death rates in the different camps is a difficult one to ascertain. (1) Some of the camps have acted as filters through which many troops have passed, leaving their most unfit on the filter. In a general way it can be stated that those camps which may be designated as closed camps and which have been least employed as filters are the healthiest camps. (2) Under similar conditions the negro is more susceptible to the acute respiratory diseases than the northern man. Southern whites are more susceptible to these diseases than are the northern whites. It is an opinion generally held by medical officers in southern camps that hookworm disease and chronic malarial infection increase susceptibility to the acute respiratory diseases. (3) There is no reason for believing that either morbidity or mortality in any camp has been due to faulty sanitation, as we usually understand this term. All the camps are kept clean, have unquestioned water supplies, satisfactory garbage and sewage removal, etc.

Comparing the National Army and the Guard, it will appear that the death rates have been practically the same among soldiers in tents and those in barracks. Comparing the National Guards of certain states and the National Army from the same states it is seen that the death rate in the National Army has, in each case, been higher than in the National Guard. This is probably due to the fact that the National Guard contained more seasoned troops than the National Army.

The diseases which have been responsible for the greatest number of deaths in the Army during the period covered by this report are the acute respiratory diseases. These may be named in the order in which they have caused deaths, as follows: pneumonia, meningitis, measles, scarlet fever and diphtheria. With the addition of tuberculosis these have caused 77 per cent. of all deaths. Sixteen per cent. of deaths have been due to other diseases, and 7 per cent. due to causes other than disease, such as mechanical injuries. The acute respiratory diseases have caused an excessive death rate in the Army compared with that due to the same causes in civil life. Pneumonia has caused by far the greatest number of deaths in the Army, and has been responsible for about 80 per cent. of total deaths caused by all the respiratory diseases. Each respiratory disease, except tuberculosis, has caused an excessive fatality in army life. It is evident that the low tuberculosis death rate in the Army is due to the elimination of those with active forms of this disease. Furthermore, it is probable that most of the deaths from tuberculosis in the Army have been due to the activation of inactive foci by acute respiratory diseases.

While both pneumonia and meningitis have exacted the greatest toll in life, they have not been as important a factor in incapacitating troops as some other causes. Measles is a large factor in this connection. The annual morbidity rate for measles for all troops in this country during the six months' period was 105 per thousand. The rate for pneumonia was 24.2, that for meningitis 4.1. Pneumonia and meningitis are the more fatal diseases and therefore, although fewer cases occur, the number of deaths is great. The fatality rate, or case mortality rate, for all troops during the six months' period has been 23 per cent. for pneumonia, 27 per cent. for meningitis and 0.1 per cent. for measles. Most numerous as causes of sickness are those less fatal ailments such as colds, influenza, bronchitis and mumps.

The National Army with its new recruits fresh from civilian life shows the highest rate in venereal diseases and meningitis. National Guard troops, however, show the highest rates for measles, pneumonia, malaria and typhoid. Regular Army troops, representing those longest in the service and in all probability an older average age, show the lowest rates in everything but scarlet fever and venereal disease, the latter being slightly above the rate for the Guard. Measles, pneumonia, meningitis and scarlet fever have existed in epidemic form in a number of the camps. Measles has been by far the most prevalent of the four. Scarlet fever has been of minor consequence. Typhoid has been a negligible factor as a cause of incapacitation. Mumps, bronchitis and influenza have likewise been widespread and although not fatal in themselves, have frequently been forerunners of pneumonia.

Vaughan and Palmer point out that to hope to reduce infection among our soldiers to the minimum without adequate attention to the health of the civilian population from which the soldier comes and with which he mingles more or less freely is without justification. All the infections which have appeared in the camps are distributed among the civilian population from which the soldiers in the camp have come. If the draft men were organized and drilled in small squads at home and gradually inducted into military life, and only those found to be free from infection sent to the camps, the control of communicable disease among the soldiers would be greatly aided. Meningitis has been most prevalent in those camps whose soldiers come from areas in which this disease has been endemic. The same thing is true of scarlet fever. Typhoid and paratyphoid occurred in only three camps and even here the incidence was very low. There were twelve camps that did not have a single case of typhoid or paratyphoid. It would be difficult to put forward testimony of a more striking nature as to the efficacy of the preventive measures now being utilized in the Army against typhoid. The American soldier today has found the army camp a safer place to dwell, so far as typhoid is concerned, than in the most favorably situated civilian community.

An extended review of the situation shows that the greatest single factor in the prevalence of disease in certain camps and their absence in others has been the natural susceptibility of the men. There have been added those aggravating factors such as exposure, fatigue, lack of warm clothing, cold quarters by day, cold quarters and insufficient bedding by night. In order to prevent a recurrence of the trouble, the authors suggest: First and foremost it seems necessary to graduate the introduction of civilians into army life. The change has been too abrupt. Men should be called first to a semiactive reserve army. Here they should get drill and the essentials of sanitation and self-care by lecture and by demonstration. The drill and calisthenics should be the hardening process. After this the transfer should be made to camp where a man's entire time is given over to his military training.

Before entering camp men should be examined for incipient disease. The suspects should be separated and watched before their dispatch to camp. Vaccination for typhoid and smallpox can be completed while in the reserve force. Once established in camp the transfer of men from one camp to another should not take place without a careful examination and removal of those who show signs of illness. This will prevent this all too frequent transportation of sick men, who are dangerous to others because of their sickness. These precautions together with care in the proper mixture of work and rest, judicial selection in the quality and balancing of the food ration, the adequate protection of the man, especially the one from the warm climate, against cold and exposure, his protection against the sick through effective quarantine measures, and discretion in the use of the physical hardening process should moderate to a large degree the experiences of the past winter.

43. **Investigations of Tropical Sunlight.**—It is by no means thoroughly established that sensitization to light in a photodynamic sense occurs spontaneously, even in the lower animals. Sellards claims that as yet there is very little evidence that such sensitization plays any significant part either in the etiology or therapy of the diseases of man.

46. **Immunity and Tissue Transplantation.**—A series of experiments in which both rabbit and guinea-pig kidney were transplanted into both rabbits and guinea-pigs was carried out by Fleisher. Guinea-pig kidney transplanted into guinea-pig shows active regeneration at an earlier period than does the same kidney transplanted into rabbits; eventually the degree of regeneration is the same in both animals. Rabbit kidney transplanted into rabbit shows far better regeneration than does the same tissue transplanted into guinea-pig. At best the rabbit kidney does not show as good regeneration as does the guinea-pig kidney. The connective tissue reaction is more marked about homoiotransplants than about heterotransplants. In general the connective tissue reaction is more marked in the guinea-pig. The rabbit seems to be a relatively better soil for the growth of guinea-pig kidney than is the guinea-pig for rabbit tissue. Fleisher failed to find evidence in his experiments that the leukocytic and connective tissue reactions are the factors of greatest importance in the poorer growth of heterotransplants, but he is inclined to believe that while these reactions may have some effect, the body fluids, through either the presence of injurious substances or the lack of substances necessary for the growth of the heterotransplant, are more important.

47. **Patient's Blood for Blood Cultures.**—According to Wurtz and Sappington the patient's blood diluted in a test tube of sterile water makes an excellent culture medium for a number of infections, at the same time furnishing the infecting organism. Evidence of this was found in fifty cases of croupous pneumonia yielding 38 per cent. of positive cultures, nineteen cases of streptococcus infection giving 47.3 per cent. of positive results, and seventeen typhoids with 64.7 per cent. positives. In pneumococcus and streptococcus infections, the method compares quite favorably with other cultural procedures; and in positive cases the bacteriologic diagnosis can be made in nearly every instance from the primary culture within twenty-four hours. In typhoid infection the bile method is superior on account of the time element, but if the slower growth is not prohibitive, the percentage of positive results with blood water will probably equal that with bile. The authors do not feel sure of the optimum dilution of blood for this work, but suggest 30 to 40 per cent. if only one tube is made, and a 5 to 10 per cent. and a 40 per cent. tube if two are taken. It is important to insure sterility of the water. The simplicity and economy of the method are obvious, and suggest its availability outside of hospitals.

48. **Circulation of Kidney.**—In contracted kidney Gross says there is a marked change from the normal in parenchymatous and vascular arrangement. The cortex is largely eliminated and has become passive, whereas the pyramids are preserved and better vascularized, possibly to take on a more active participation in the work in the kidney than in the normal physiologic sphere. This means renal insufficiency and perversity. It is justifiable to assume that these, together with the concomitant metabolic disturbances, gradually upset the economy of the whole organism, and ultimately are, at least largely, responsible for uremia and death.

49. **Unusual Blood Cells in Diseases of Bone Marrow Origin.**—In making a routine examination of the blood of a dispensary patient, the examination of the stained smear brought to light an unusual blood picture. The smears, from which the drawings were made, were stained with Hastings' modification of the Nocht-Jenner stains. The hemoglobin with the Dare was 45 per cent. The red cell count was 1,500,000. Index was high, that is 1.5. White blood cells numbered 4,000 to 5,000. In counting 300 leukocytes an equal number of nucleated red cells was noted down. Nucleated red cells of the three ordinary types were seen, that is, normoblasts, intermediates and megaloblasts. The cell called Turck's stimulation form was also present. The cells that interested Thro particularly correspond to the descriptions of Naegeli's myeloblasts or Turck's lymphoid marrow cells. In Thro's experience only one other case with pernicious anemia had a blood picture like the one described. These two patients had all the blood changes of pernicious anemia with the addition of cells characteristic of those found in so-called acute lymphatic leukemia, and it seems such are correctly designated by calling them cases of leukanemia.

50. **Grafting of Tissues.**—Loeb states that tissues transplanted from parents to children or from sisters and brothers to sisters and brothers, or from children to parents, behave in a manner intermediate between tissues after homoiotransplantation and autotransplantation. The difference between results obtained after transplantation from parents to children, and after transplantation of tissues from an animal to his sisters and brothers, is so small that it may be entirely accidental. Tissues transplanted from children to mother also show an intermediate behavior. All degrees of variation between the two extremes of results resembling those in autotransplantation on the one hand, and of homoiotransplantation on the other hand, are obtained after transplantation of tissues into near relatives.

52. **Experimental Production of Lesions.**—In all the rabbits injected by Friedman with pilocarpin, lesions, erosions, or acute ulcers were demonstrated in the mucosa of the stomach. In the rabbits injected with pilocarpin and epinephrin, lesions in the mucosa of the stomach and duodenum were evident. From these experiments it is clear, therefore, that through repeated injections of pilocarpin alone, lesions or acute ulcers were obtained in the stomach, while alternate injections of both pilocarpin and epinephrin produced in addition lesions or erosions in the duodenum.

59. **Antipneumococcus Serum Treatment of Lobar Pneumonia.**—Kyes reports 115 cases of acute lobar pneumonia in which the patients were treated with an antipneumococcus serum, and compares the mortality among these cases with the mortality in 538 similar cases of pneumonia occurring in the same institution during the same period, but not so treated. The antipneumococcus serum was produced by injecting massive doses of virulent pneumococci into the domestic fowl. Of the 538 patients not treated with the antipneumococci serum, 244 died—the death rate being 45.3 per cent. Of the 115 similar patients treated with the serum, twenty-four patients died—the death rate being 20.8 per cent. In the ward in which the serum was employed the death rate during the six weeks prior to the introduction of the serum treatment was 55 per cent. During the six weeks subsequent to the withdrawal of the serum treatment, the death rate was 51 per cent. These statistics show that among those cases treated with the antipneumococcus serum the death rate was less than one-half the rate obtaining among the similar cases not so treated, be they cases occurring in other wards during the same period, or in the same ward at other periods of the same year. This is the essential proof which Kyes has to offer that the antipneumococcus serum in question is of distinct value in the treatment of acute lobar pneumonia in man.

60. **Primary Hydronephrosis.**—A study of their material showed Geraghty and Frontz that the most frequent cause of so-called primary hydronephrosis is an inflammatory contraction at the ureteropelvic junction, and that more careful microscopic study of this region in cases of hydronephrosis, without apparent cause, will disclose this lesion in a large percentage of them. In many cases in which aberrant blood vessels, renal mobility, or abnormal implantation of the ureter have been assigned as the cause of the hydronephrosis, careful examination of the upper ureter and pelvis will reveal inflammatory narrowings which have unquestionably played the primary rôle. When the kidney is extensively destroyed, nephrectomy, if not contraindicated, should be carried out. When the kidney, however, possesses valuable renal function or when a bilateral condition contraindicates nephrectomy, the various plastic procedures outlined above offer considerable prospect of success.

61. **Absorption of Drugs from Bladder and Urethra.**—Macht's experiments showed that a large number of drugs and poisons can be and are absorbed from the urethra, and that the absorptive power of the bladder is very poor as compared with that of the urethra. A review of clinical evidence agrees with the experimental findings. Poisoning through the urinary tracts has been reported and is not uncommon. The absorption of a large number of drugs and poisons—alkaloids, antiseptics, salts and local anesthetics—from the bladder and the urethra in the male was studied.

79. **Food Anaphylaxis and Methods of Making Tests.**—There are two accepted methods of conducting the anaphylactic food tests. (1) The endermic and (2) the intradermic. Strickler prefers the intradermic method which consists in the introduction of a solution of a food protein in the layers of the skin by means of a hypodermic needle. As a result of this procedure a white wheal is produced at the point of injection and often there is a reddened zone around the blanched spot. This is conceded to be the most delicate method which can be employed in conducting the endermic skin test. The amount injected in this method is 0.1 c.c. In none of Strickler's cases were there any evidences of a constitutional reaction of any nature whatever. He adopted the following standard as to what constituted a positive reaction. (1) A papule must be present at the point of injection. (2) In the vast majority of cases a zone of erythema is found around the papule. (3) Tenderness is often found at the point of injection. (4) The lesion must persist for more than twenty-four hours after the injection. Wait for forty-eight hours before reading the reaction. Strickler studied fifty-four patients with eczema and the great majority of them were kept under observation for some weeks. The following proteins were employed: cow casein, egg, beef, mutton, pork, chicken, fish, oysters, clams, crabs, wheat, oatmeal, rice, barley, tomato, and strawberries. The protein is extracted by the use of weak alkali, and after shaking and incubating the solution it is filtered, absolute alcohol is added, and the solution evaporated on a water bath. A saturated solution of this dry material is made in an alkalinized sodium chlorid solution. These preparations were tested for sterility, and for their nitrogen contents by the Kjeldahl method. Twenty-eight patients were in a greater or lesser degree benefited by a changed diet, as shown by the anaphylactic food test. In thirteen cases the food tests were entirely negative, and in the remainder the correction of diet, as shown by the food tests, did not have any influence on the disease. Of thirteen patients with urticaria, eleven showed positive anaphylactic food reactions, while two were entirely negative. In this series five were acute and the remaining eight were chronic cases. In the acute cases the removal of the offending article caused a rapid subsidence of the eruption, and these tests serve as a guide to ward off further attacks. Of eleven patients suffering with psoriasis, four gave positive reaction and seven were entirely negative. Only in one case was there some improvement in the eruption following the installation of corrected diet. Strickler studied sixteen patients suffering with acne vulgaris and three with

acne rosacea Five showed negative, the remainder positive reactions. In none of the cases, although most of them were kept under prolonged observation, did any noticeable improvement follow the corrected diet.

7. **Treatment of Septic Wounds.**—Robinson describes a method of keeping wounds elevated as well as compressed. He says that it allows of a complete toilet. The bactericidal serum enhances the defensive properties of a wound, which, as is well known, are at a high state of development at the time of infection. During the progress of healing the perfect immobility of the compressed area, since all circumferential forces are inhibited at the line of constriction, gives the best condition possible for the building up of healthy scar tissue. The part inside of the constricted area is free from any kind of traction, and the edges of the wound are quite flaccid and tend to fall together.

Of equal importance in the healing process is an avoidance of anything that would tend to depreciate the vitality of the growing cells. The practice of packing a wound with an unabsorbable dressing, such as sterilized gauze, is a familiar example of the continued disturbance of growing granulations wherever such a dressing is removed; not only is the proceeding exceedingly painful, but a layer of germinal tissue is taken away in the dressing to which it has adhered. This, of course, means delay, and what causes delay will eventually show in the final cicatrix. It is urged, too, that germicides in destroying bacteria must in some measure impair the vitality of the surrounding cells; it is considered improbable that the bacterial protoplasm should be killed outright, and that the protoplasm of the neighboring cells should escape untouched.

Many years ago Robinson invented a dressing from cancellous tissue of bone. This is deprived of fats, decalcified and bleached, and forms a soft white sponge-like tissue which adapts itself readily to the soft parts. It is both absorbent and absorbable. Though its utility has been circumscribed and limited, it is still a most serviceable dressing for chronic wounds. It fails in freely secreting wounds, as it does not provide sufficiently for drainage. Robinson thinks that if modified the matrix of bone tissue will ultimately form a basis for dressings.

11 Enemy Air Raids on Canadian Hospitals, May, 1918. J. G. Adami.—p. 64.
12 *Diagnosis of Chronic Infections with Gonococcus by Complement Fixation Test. F. B. Bowman and P. D. Saylor.—p. 73.

12. **Complement Fixation Test in Diagnosis of Chronic Gonorrhea.**—The specificity of the complement fixation test for gonorrhea is confirmed by Bowman and Saylor. They state that in cases in which a large amount of pus is present and intracellular gram-negative cocci are numerous, a diagnosis of gonorrhea can be accepted. But in cases in which there is no discharge, or very little, with very few bacteria present, a positive diagnosis of gonorrhea cannot be given. Three hundred and eighty-three tests have been made. Of these, 177 were positive; 77 patients gave a definite history of having had gonorrhea, and 60 of these were strongly positive and 17 negative. Of 36 cases diagnosed as epididymitis, 19 were positive, 17 were negative; of 20 cases diagnosed as prostatitis, 14 were positive, 6 were negative; of 21 cases of orchitis, 15 were positive, 6 were negative; of 4 cases of chronic gleet, 3 were positive and 1 negative; 3 cases diagnosed as rheumatic fever were positive; of 26 cases with a clinical diagnosis of myalgia and no clinical evidence of gonorrhea, 8 were positive and 18 negative. A Wassermann test was made on each of these specimens; 25 were positive, and all of these had had syphilis, or clinical evidence of this disease was actually present. The authors found no evidence of cross fixation in this series of tests. The gonorrheal test is never positive in localized anterior urethritis, nor is it usually positive before the sixth week of the disease if no complications are present. A patient should not be considered cured if the test is still positive, even *two months* after the disappearance of all symptoms.

13 *Treatment of Malaria. R. Ross.—p. 241.
14 *Quinin Prophylaxis in Malaria. L. Rogers.—p. 249.
15 Treatment of Malaria by Quinin: Failure of Splenox. E. H. Wright.—p. 252.
16 Quinin in Malaria Prophylaxis. K. D. Pringle.—p. 258.

13. **Treatment of Malaria.**—From the results of treating 1,040 old cases of malaria with antirelapse quinin prophylaxis, it would appear that comparatively small doses, amounting to about 60 grains a week, distributed in various ways, reduce relapses to about 10 per cent. of the cases per month, and also diminish the severity of the relapses when they do occur. But 5 grains daily seem less effective and 15 grains daily are no more effective than 10 grains daily and less well borne by the patients. Ross has not been able to note any marked superiority in any one of the three modes of administration of quinin—oral, intramuscular or intravenous—as regards either the speedy reduction of the fever and the parasites (in relapses), or as regards complete sterilization of cases. Harrison's method of using oral and intramuscular administration together is valuable when large dosage is employed. Several medical officers favor complete rest in bed during treatment, even for two or three weeks, especially when large doses of quinin are being given. Generous diet and a little beer or wine are usually given. Arsenic and iron are also favored for the later stages of treatment, but it has not been possible as yet to obtain decisive statistical evidence in support of any of these views. Out of the total of 2,460 cases studied here, 682 or 27.7 per cent. are known to have relapsed either during treatment or afterward.

14. **Quinin Prophylaxis in Malaria.**—Rogers believes that in places where the great majority of the inhabitants are already infected with malaria, as shown by a very high endemic index, quinin prophylaxis has little scope except in the case of European and other immigrants, among whom it

is of the utmost importance, but for the general population full curative treatments with quinin, preferably once a quarter, are necessary materially to reduce malaria.

Quinin prophylaxis to be successful should be based on the following principles: (*a*) A sufficient dose should be given to kill all the invading parasites, so as to avoid the danger of any quinin resisting form surviving and making the fever more difficult to cure. For this purpose not less than 10-grain doses are indicated. (*b*) The intervals between the doses should not exceed two days less than the mean incubation period of the most rapidly developing form of malaria present, which will almost invariably be the malignant tertian variety with a mean incubation period of six days and a minimum of two days. The interval should therefore not be less than four days, and if an epidemic is present this should be reduced to two days. (*c*) The prophylactic doses should be given on two consecutive days as a rule so as to act on the stage most amenable to quinin of each brood of a double infection.

The causes of the frequently reported failures of the two most commonly employed methods are: (*a*) in the case of Koch's biweekly doses on two consecutive days with a five-day interval, that the interval is too long in the case of malignant tertian malaria, especially when of a virulent form; (*b*) in the case of daily 5-grain doses, that the dose is too small to be certain to destroy all the parasites. To be effective as a prophylactic against malaria, quinin should be given in not less than 10-grain doses on two consecutive days, with an interval of not more than four days without the drug, and in highly malarious places the interval should be reduced to two days and the dose increased to 15 grains. Ten grains every other day has also proved successful.

23 Students' Number, 1918-1919.—p. 259.

18. **Treatment of Wounds.**—The Carrel-Dakin treatment of wounds is strongly endorsed by Morrison and his associates. Two hundred cases form the basis of this paper. The first 100 were patients treated in a base hospital in the wards devoted to the most serious cases; the second 100 in the surgical observation hut attached to a general hospital. These last consist of severely wounded men, moribund cases being excluded. Results vary greatly according to whether preliminary surgical treatment is undertaken in the preinflammatory period or after sepsis is established. The cases are therefore divided into (*A*) those patients operated on within twenty-four hours, and (*B*) those without preliminary operative cleansing, or in which this was not done till at least twenty-four hours had elapsed. Far better results were obtained in the Class A cases than in the Class B cases. This method of wound treatment is compared with other popular methods now in use greatly to their disadvantage. The proportion of really successful cases (that is, where secondary suture in the first ten to twelve days permits practically of a return to normal) is higher far than that attained under any other treatment thus far tested. The only other method giving results at all comparable is that of early operation and primary suture with or without the use of brilliant green, bipp, flavine, soap, or other fashionable adjuvants.

The authors conclude their report by saying that the dichloramin-T oil method of wound treatment is simple of application, and the claim that the action of a single application is prolonged is substantiated. The results, even when judged by modern standards, are not to be disregarded. Dichloramin-T oil is not indifferent to granulation tissue or to the skin edges of wounds, but has, especially if used for a long time, a deleterious action on both. The ingrowth of skin is retarded, and the natural tendency for granulation tissue to disorganization is aggravated. The use of an oily menstruum does not altogether prevent the adhesion of dressings to the surface or obviate the repeated, if minute, insult to the tissues inseparable from each dressing. Though an improvement on some other methods in vogue, dichloramin-T oil has not yielded the improvement on neutral solution of chlorinated soda that was anticipated, perhaps because it is neither innocuous to healthy granulation tissue, nor a solvent of dead tissue; perhaps, possibly, because an oily application is not so efficacious as a watery solution in the treatment of wounds.

21. **Blood Pressure Measurements.**—Experience has shown great practical clinical value of blood pressure measurements in connection with a limited number of conditions, namely, arterial and renal diseases, cerebral pressure, pregnancy toxemias, Addison's disease, and, to less extent, aortic insufficiency. Before attributing pathologic significance to the measurements, however, Kilgore says, wider normal limits (both systolic and diastolic) should be recognized than those generally indicated in the books. Figures from normal young adults are presented in substantiation of this statement. An important and little known application of the blood pressure apparatus is its use in the detection of pulsus alternans. It is urged that systolic pressure be retained as the most important measurement, and that the simple palpatory technic be used. Blood pressure determinations in general have fallen short as clinical indicators of circulatory function. Pulse pressure, and consequently the various formulas in which it is involved, depends on too many factors to be a very useful index for any of them. Great variation is shown among pulse pressure measurements of normal persons. The same criticism is shown to be applicable in the case of the auscultatory tone phases.

29 Present Status of Lobar Pneumonia. Van Reeth.—p. 195.

24. **Malaria and Other Tropical Diseases in the Balkans.**—Castellani comments on the wide variety of clinical pictures presented by malaria in the Balkans. This is puzzling for medical men not familiar with tropical diseases. There is no internal disease that malaria may not simulate, and it may even induce a set of symptoms deceptively suggesting acute surgical affections. He reviews his experience and relates typical cases of each type, including pseudopurpura, sleeping sickness, cholera, cirrhosis, appendicitis, cholecystitis and pancreatitis—for all of which malaria was responsible, as also in 90 per cent. of some epidemics of alleged typhus. Among diseases other than malaria, trench foot has been encountered, like that in France, spirochete bronchitis and jaundice. Dysentery, typhoid and tropical skin diseases are common, as also pellagra in certain parts of Macedonia.

25. **Tuberculosis of the Middle Ear.**—The young soldier had been at the front for two years, apparently healthy, when otitis media developed and proved to be of tuberculous origin, secondary to an unsuspected lesion in the lung. Tits is convinced that tuberculosis would be found responsible for otitis media in a larger proportion of cases if it were suspected in the torpid chronic cases that have no acute onset. He warns further that examination may give negative findings as in this case. Only when the examination was repeated several times were the results conclusive.

Bulletin de l'Académie de Médecine de Paris

Sept. 3, 1918, **80**, No. 35

30 *Comparative Resonance of Tuberculous Apex. E. Boinet.—p. 196.
31 *Mumps. L. Captan.—p. 197.
32 *Aeroplane Surgical Unit. A. Nemirovsky and Tilmant.—p. 202.
33 *Syphilitic Peritonitis. M. Letulle.—p. 209.

30. **Resonance of the Apex.**—Boinet describes how percussion can be made most instructive to detect changes in the resonance and transsonance of the apexes.

31. **Mumps.**—Capitan analyzes his experiences with 700 cases of mumps in the troops. Careful bacteriologic examinations demonstrated, he says, that mumps is a polymicrobian infection of the blood. In some of the cases lymph nodes below the salivary glands became swollen and even suppurated, and bronchitis up to pneumonia was also occasionally encountered as part of the clinical picture. The spleen was almost invariably enlarged. Orchitis was observed in 16 and 15 per cent. of the cases before 1918, but during this year the proportion has been 25 per cent. The disease has been a little graver on the whole this year, and the complications more frequent. In some rare cases there was a rubeola-like eruption, and in six cases meningeal symptoms developed, relieved by lumbar puncture. All these complications of mumps proved mild. The early hypertrophy of the spleen may aid in the differential diagnosis.

32. **Aeroplane Surgical Unit.**—As mentioned in the Paris Letter, page 1155, a flying surgical unit has been devised by Nemirovsky and Tilmant. The specifications were filed with the Ministère des Inventions, Feb. 21, 1918. The success of the aeroplanes devised to carry the wounded to the surgeon soon suggested the advantages of conveying the surgeon to the wounded, and this "aerochir" is the result. It aims to bring to the first aid stations, to advanced posts without roentgen equipment, a well equipped surgical and roentgen outfit, and aid advanced posts overwhelmed by the influx of wounded beyond what they had been organized for.

The aerochir is designed to carry, besides the pilot, a surgeon and a radiologist to serve as assistant to the surgeon, and all the roentgen and surgical material for all kinds of interventions. The motor of the plane can supply the power for the roentgen current with the interposition of a small transformer and interrupter. It can serve also for electric sterilization, or a storage battery can be utilized for this. The apparatus are light and portable so that they can be readily carried into a first aid post or other surgical station and set to work at once, or they can be used in connection with the aerochir itself. The apparatus are not described in detail, but the advantages of a flying radiosurgical unit, alone or in squadrons, are emphasized, especially the rapidity with which surgical aid can be brought, the fact that the roads are left free just at the time when they are liable to be most clogged, the speed of transit and the fact that the wounded is spared the transportation, having aid brought to him in the swiftest and most complete manner. In urgent periods the aeroplane could return to headquarters for a new outfit, so that one or two of these aerochirs could serve for 200 kilometers of the fighting front and no spot would be more than two hours away when summoned by telephone. The radioscopic and radiologic manipulations not requiring the patient to be undressed could be done in the aeroplane itself. With the cap devised by Dr. Mondain to be used with Nemirovsky's compass, the projectiles can be located in full daylight. This compass as well as any surgical instrument needed can be placed in the aeroplane without cumbering it.

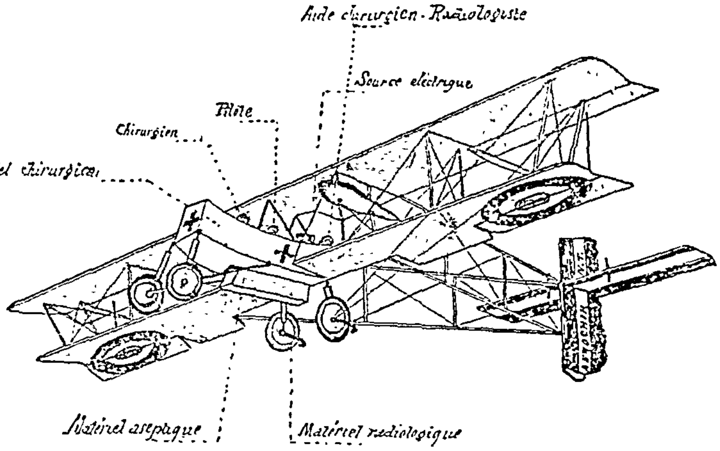

Fig. 1.—Roentgen-surgical aeroplane "Aerochir."

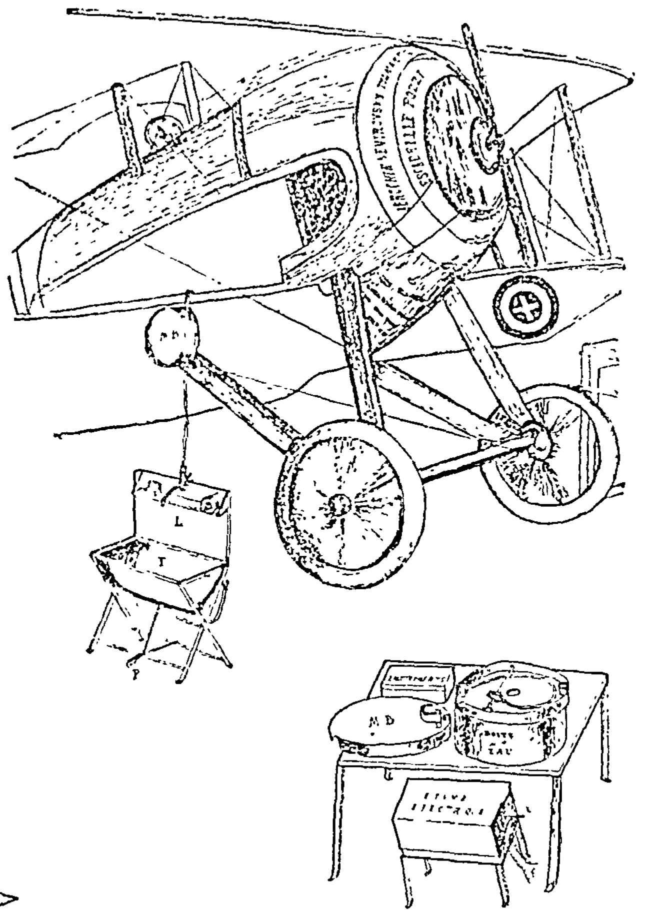

Fig. 2.—Folding washstand, instrument stand and electric sterilizer.

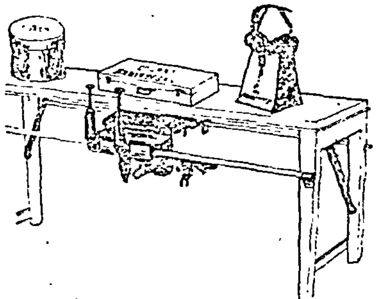

Fig. 3.—Roentgen table with compass for locating projectiles.

33. **Syphilitic Peritonitis.**—Letulle devotes twenty-one pages to this preliminary communication on the frequency of syphilis as a factor in the development of ascites with cirrhosis of the liver. In a recent series of 152 cases of cirrhosis of the liver he found the Wassermann test positive in about 49 per cent. of the cases. His research has further demonstrated that the peritoneum is frequently the favorite culture soil for the syphilis spirochete. Syphilitic peritonitis is usually secondary to some inflammation of the liver, either a syphilitic affection of the liver or simple diffuse cirrhosis hitherto erroneously ascribed exclusively to abuse of alcohol. This secondary syphilitic peritonitis may extend throughout the whole peritoneum, but as a rule it is partial, circumscribed in special regions, around the liver, cecum, colon, etc. Whatever the extent of the lesions and their microscopic texture, this specific seritis, as he calls it, long respects the structural integrity of the organs which it covers with its fibroid shell, but finally they may become involved in its cicatricial retractions. These retractions and the consecutive atrophy at points of the peritoneum may entail redoubtable complications, and

their true nature and the outlook should be understood in the study of abdominal pathology. He gives illustrations of some typical findings; the chronically inflamed serosa throws up a hypertrophic sclerosis, and from this exudes the progressive ascitic effusion so familiar to the clinic.

45 *Valvular Disease and Fitness for Service. A. Clerc and H. Aimé.—p. 516.
46 *Intraspinal Lavage in Meningitis. G. Rosenthal.—p. 521.

34. **Lethargic Encephalitis.**—In the first of the two cases reported the young woman died the ninth day after the first symptoms, diplopia, slight headache, with complete bilateral ptosis the third day, with increasing somnolency. The other young woman was four months pregnant, and the symptoms at first were profound apathy, immobility of the facial muscles, catatonic retention of attitudes, and torpor to such an extent that she seemed to be constantly asleep with the eyes open, but there were no ocular symptoms. There was a slight rise in temperature the sixth week and the woman died at the end of the seventh week. In the discussion, Netter emphasized the differences between this lethargic encephalitis and poliomyelitis, and stated that the British have already reported 105 cases. Marie described the histologic findings in the above two cases. To the naked eye the brain seemed normal, but the microscope revealed in both a small focus of subacute inflammation in the locus niger (substantia nigra or intercalatum), spreading toward the ganglions of the base and to the gray matter close to the ventricle in the protuberance and the bulb. The lesion was strictly limited to the juxtaventricular gray matter, the nuclei around being apparently sound.

35. **Tardy Relapse of Meningitis.**—The relapse occurred four months after defervescence, but the man had not felt well in the interim. The relapse occurred after antityphoid inoculation, and the case suggests that men who have had meningitis should be spared the antityphoid inoculations. During his convalescence he presented the symptoms and aspect of general paresis, and recovery was very slow. He was finally discharged as unfit for duty.

37. **Pleural Effusions.**—Petzetakis explains that the eosinophils and basophils found in an aseptic pleural effusion are formed on the spot at the expense of the polynuclears, etc., of the effusion. He calls this *eosinoplassic*.

38. **Cholesterol Deposits in Joints.**—Loeper and Verpy found deposits of cholesterol crystals in the connective tissue, synovia, and in the synovial fluid in a man of 47 with deform- ing polyarthritis of the fingers and wrist who had succumbed to aortitis. There were also similar deposits in the aorta. Cholesterol deposits were also found in a soft tumor from a woman of 39 with old and extensive deforming rheumatism. In a third case the man had gouty tophi in addition to the deforming rheumatism. In a hygroma removed from the shoulder, there was an enormous proportion of cholesterol crystals with uric acid crystals. They add that to determine the nature of a deforming rheumatism it may be necessary to apply chemical tests to the deposits in the joints. Treat- ment would vary then according as the tests reveal, singly or combined, carbonophosphates, oxalates, uric acid or cholesterol.

40. **Icterohemorrhagic Spirochetosis.**—Two more cases are reported of the meningeal form with subjaundice, with complete recovery.

44. **Hemolytic Index.**—De Verbizier and Marchand discuss the hemolytic index of human serums in connection with the "rapid" technic for the serodiagnosis of syphilis. Their research in 300 cases has confirmed the conclusions of Hecht-Weinberg in respect to the necessity for ascertaining the hemolytic index as a preliminary to the test.

45. **Valvular Disease and Fitness for Service.**—Clerc and Aimé comment with approval on the recent regulations which specify that men with valvular disease should be dismissed from the army temporarily or permanently as the commanders are unable to maintain a stable system for sedentary limited service. Occasionally this may deprive the army of the services of some man who might have stood the strain, but the army as a whole has only gained by it. In the present condition of things it is better to renounce a few than to expose the large number of men with valvular disease to the nefarious consequences of the strain of army life.

46. **Intraspinal Lavage.**—Rosenthal reports a case of cerebrospinal meningitis with the *Meningococcus crassus* which confirms the advantages of rinsing out the spinal cavity with saline and citrate solution. The solution is introduced until it comes away clear, first the 38 per cent. solution of sodium citrate; then simple saline; then the chlorocitrate solution: 7 gm. of sodium chlorid and 8 gm. of sodium citrate to the liter. A very fine needle is introduced inside the ordinary lumbar puncture needle, thus ensuring the two-way current. In the case described, the thirty-first lumbar puncture showed normal spinal fluid, confirming the clinical recovery, over two months after the first symptoms. Disinfection of the nasal fossae formed part of the treatment. The disease had run its course in waves.

The spinal cavity is rinsed out with the simple saline, introducing it 20 c.c. at a time. With patience, up to 100 or even 160 c.c. can thus be used to flush the spinal cavity, using the chlorocitrate solution only for the last two syringefuls. Sodium citrate checks the production of false membranes, and a little of the chlorocitrate solution is left in the spinal cavity at last to facilitate this action. The strong citrate solution is liable to cause transient pain, and hence should be rinsed out carefully.

47 *Cicatricial Stenosis of Esophagus. L. Sencert.—p. 553.
48 Resection of Left Angle of Colon for Cancer. Desmarest.—p. 575.

47. **Cicatricial Stenosis of the Esophagus.**—Sencert refers to absolutely impassable stenosis or stenosis which is not constantly and easily permeable. The simple, effectual and certain treatment for such cases, he declares, is a gastrostomy with retrograde "endless" dilatation. He describes in detail how to overcome the difficulties encountered in this, with typical cases from his total experience with fourteen cases. One illustration shows the cardia as seen by direct gastroscopy through the gastrostomy opening. Another shows the young man with the thread left emerging from this opening and through the mouth.

56 *War Wound of Knee. Monprofit and L. Courty.—p. 49.
57 *Treatment of Psychoses with Convulsions. G. Aymes.—p. 56.

53. **Shock.**—In order to get a better idea of the nature of shock, Blechmann has had each case investigated and the data recorded on a systematic plan. The chart listed each of the seven reflexes tested, the oscillometer maximal and minimal pulse, the oculocardiac reflex, the blood viscosity, coagulation and hemoglobin, lumbar puncture; white der-

mographism, etc.—over forty kinds of data from the examination being thus recorded on the chart by a uniform plan as the patient is being undressed, heated and morphinized. The oscillometer is particularly convenient for repeated determination of the blood pressure in the wounded, as it can be applied to wrist or ankle. On each chart is recorded also the clinical impressions of the phases through which the patient passes. These records have aided in establishing that the state of shock is not due to the hemorrhage or to any single cause but to the combination of the concussion, the pain, hemorrhage, etc., and superposed on these the anesthesia, the operative shock and toxi-infection. He adds that Crile's and Roger's researches have proved the Ariadne's thread that has led us at least to warm up the wounded and give some preoperative treatment, watching over the evolution of the shock by the behavior of the blood pressure.

54. **Autogenous Vaccine for Brain Wounds.**—The pulsation in the brain aids in the expulsion of small splinters and foreign bodies, but the brain has very little power of defense against infection. To enhance this by an autogenous vaccine specially prepared to act on brain tissue, Moulonguet took the microbes for it from the brain lesion itself, and added human or bovine brain tissue to the culture medium. The twenty-four hour culture was emulsioned in physiologic solution and heated to 60 C. for an hour. This brain autovaccine was then administered by subcutaneous daily injections. One culture tube provided three ampules, and he injected half an ampule the first two or three days and then a whole ampule after this. He has applied this treatment only in three cases to date, but the improvement was so marked under it, as he describes in detail, that he does not wait for further confirmation to commend this treatment as a prophylactic measure after an operation on the brain, to prevent the development of infection or aid in curing it if it has developed, especially in cases of subacute and chronic encephalitis, and after operative treatment of a tardy abscess in the brain developing around a splinter or projectile. He adds that this vaccine may render good service also after an operation on a brain abscess of otitic origin, or in preventing its development.

56. **Perforating Wounds of the Knee.** — Monprofit and Courty tell how during the first years of the war arthrotomy, even very extensive, gave such bad results with wounds of the knee that many of the men evacuated apparently in good condition had to be amputated in the reserve hospitals. Much better results were realized when, instead of opening up the joint widely, it was merely punctured to release the extravasated blood and effusion, or extract the projectile with the least possible injury to the tissues, and then sutured and immobilized. The synovial membrane does not stand well exposure to the air, and the joint heals far better when the synovialis is sutured at once with catgut and the skin with silk. When the bones are so injured that resection is necessary, it should be the typical resection. This averts amputation, drains well and gives good orthopedic results. In his 16 cases the cure was complete in 15, one man requiring amputation on account of tetanus. In Tuffier's 108 cases of resection the knee was firm with slight mobility in 11 cases, with complete ankylosis in 93; the joint was loose in 5 cases.

57. **Treatment of War Psychoses with Convulsions.**—Aymes has been impressed with the improvement under calcium chlorid associated with a hypnotic in treatment of war psychoses with convulsions. He describes the details of the twelve cases given this combined treatment.

59 *Sepsis from the Mouth. Dufourmentel and L. Frison.—p. 145.
60 Extension Treatment of Bones in Hand. Lance.—p. 416.

58. **Echinococcus Cysts.**—Dévé describes the origin of and the pathogenic conditions inducing daughter cysts, saying that so long as the mother cyst is in a quiescent state there is no production of daughter cysts until the mother cyst is growing very old or its contents become infected or stained with bile, or the fluid contents are evacuated. All of these causes become more likely with the increasing age of the cyst. It is important to ward off these different causes for production of daughter cysts, especially refraining from puncture. The cyst should be removed at the earliest possible moment, and we should seek for echinococcus cysts in dubious cases, even in children, as a routine measure. Many cases of cysts in adults date from childhood.

59. **Sepsis of Buccal Origin.**—The three cases reported proved fatal. In one there was a toxic cellulitis of the neck, and in one phlebitis of the craniofacial vessels. The primary lesion had been an acute gingivitis or abscess at the root of a tooth, and the resulting septicemia proved fatal in from two to eighteen days.

63 *Retarded Primary Suture of War Wounds. A. Chalier.—p. 229.
64 *Traumatic Lesions of the Arteries. G. Jeanneney.—p. 230.

61. Summarized in abstract 38.

62. **Soldiers' Irritable Heart.** — Clerc and Aimé discuss recent literature on this subject. A hyperexcitability of the entire sympathetic system seems to be the actual cause of the irritable heart and the instability of the circulation and secretory processes which generally accompanies it. A constitutional predisposition or the effect of some infection is the primary factor.

63. **Primary Suture of War Wounds.**—Chalier insists that it is possible to apply the primary suture even as late as twelve hours after the wound when clinical observation shows that the wound is little if any infected. In 32 cases he operated and sutured between the thirty-fifth and fortieth hour in 3; to the forty-eighth hour in 9; third day in 7; and from the fourth to the eleventh day in 13. In only 3 of the total 32 was it necessary to open up the wound again. In all the others the scar was linear and supple as with the finest early sutures. A number of the men returned to the front in less than a month, and yet the wounds had been serious ones, some including the skull, others large arteries; in 17 cases projectiles had to be extracted.

64. **Traumatic Lesions of Arteries.**—Jeanneney expatiates on the convenience and advantages of the Pachon oscillometer as a means to estimate the blood pressure and the diagnosis and prognosis of war wounds of arteries. Some lesion of the artery may be assumed when the oscillometric curve is lower and shorter than on the sound side. It shows whether the circulation below a ligature is growing better or worse, and thus is a guide to treatment and for the prognosis. Besides its practical value along these lines, it throws light on the vasomotor mechanism of the phenomena accompanying vascular lesions.

67 Personal Prophylaxis of Diphtheria. F. Brandenberg.—p. 1106.
68 *Influenza. E. Lanz.—p. 1108.

65. **Paroxysmal Tachycardia.**—Roth describes five cases of sinus tachycardia, and says that in all he was able to arrest the attack of tachycardia by applying mechanical irritation to the vagus nerve. The simplest method for the purpose was found to be compression of the cervical portion of the vagus nerve. To ward off recurrences he gave small doses of a preparation of digitalis three times a day.

68. **Influenza.**—Lanz comments on the frequency of pneumonia in the present epidemic of grip. The rusty sputum of pneumonia and a crisis are seldom observed, but reduction of the chlorids in the urine and their return to normal at once when the process is arrested are reliable bases for diagnosis and prognosis. No benefit was derived from acetylsalicylic acid, optochin or salvarsan, but a mixture of digitalis, sodium salicylate and antipyrin salicylate every two hours seemed to check the spread of the pneumonia process by the intense

external male pseudohermaphrodite, but the general aspect was altogether feminine. The swelling in the groin was the undescended testicle. Two of the three sisters were of the same external male pseudohermaphrodite type, and probably likewise a maternal aunt. Lunden discusses the physician's conduct in such cases of *erreur de sexe*. He advocates removing the testicles, as they are liable to undergo malignant degeneration. The patient should be informed, he thinks, that there is malformation which would prevent child bearing, and consequently that she should not marry. It is better not to specify the nature of the malformation.

105 *Invagination of Child's Intestine. N. Barth.—p. 784.
106 Breaking Up of Pleural Adhesions. W. Holmboe.—p. 799.

102. **Phenolsulphonephthalein Test of Kidney Functioning.**—Motzfeldt reviews the literature on the phenolsulphonephthalein test and his own experience with 212 applications of the test on 136 patients at the Rikshospital. Only 61 of the patients had kidney disease. In 54 with sound kidneys, from 40 to 70 per cent. was eliminated during the first two hours: the average was 65 per cent. and it was never below 50 per cent. The elimination was entirely independent of the amount of urine during the two hours, the percentage keeping the same when the subjects had been drinking a liter of water half an hour before the test, as also in a case of renal dropsy in which the output of urine increased from 1,500 c.c. one day to 8,000 c.c. a few days later. The phenolsulphonephthalein output was 35 per cent. on both these days. The findings in the 61 patients with nephritis are tabulated under different headings, and are compared with the symptoms observed.

He extols the simplicity and reliability of the test; a positive response testifying to functional impairment of the kidneys. Nephritis may exist without appreciable functional impairment, and hence negative findings do not exclude nephritis. He found evidences of retention of nitrogen in every case when the output of the phenolsulphonephthalein was below 25 per cent. The test is thus peculiarly useful in differentiating between the true and the spurious form of uremia, the *azotémic* and *chlorurémic* of the French writers. On the other hand, there is no connection between the elimination of phenolsulphonephthalein and albuminuria, edema or high blood pressure.

103. **Eclampsia.**—Brandt analyzes the twenty-seven years' record of the Christiania obstetric and gynecologic clinic. It includes 431 cases of eclampsia. In the 156 cases since 1906, there was a mortality for the mothers of 14.1 per cent. and for the children of 27.3 per cent. in the 121 cases in which the eclampsia developed before or during labor. The figures are, respectively, 25.7 and 2.5 per cent. in the cases with postpartum eclampsia. The Stroganoff prophylactic method is applied as the routine measure, that is, keeping the woman under the influence of moderate doses of morphin and chloral and protecting her against noise and light. Venesection is done when necessary, and also lavage of the stomach. Otherwise she is left in peace. If the convulsions keep up, Brandt does not push this Stroganoff method to the extreme, but delivers the woman under deep ether anesthesia, with forceps, cesarean section or otherwise as indicated. One great advantage of the Stroganoff treatment is that the general practitioner can apply it with the help of the obstetric nurse, who can keep him posted by telephone as to the patient's condition. Some recent German publications report from the Charité at Berlin 17.2 per cent. mortality in 501 cases of eclampsia, before 1912, given purely operative treatment. Since then, 168 cases given the Stroganoff and venesection treatment showed a mortality of 14.3 per cent. for the mothers and 36 per cent. for the children. Pregnancy eclampsia was found to give the most unfavorable results. Bumm also has reported that operative treatment has not fulfilled expectations, and since 1911 treatment has been expectant. The pure Stroganoff treatment in his hands gave 44 per cent. mortality. The total mortality in 567 cases was 17.3 per cent. Necropsy revealed irreparable changes in liver, kidneys and brain. It is stated that venesection is called for only in pregnancy eclampsia. In institutions, primary operative treatment seems to be preferable.

104. **Double Uterus.**—In removing an ovarian cyst, Haugseth accidentally discovered that there was a duplex uterus bicornis with vagina septa. The woman had had seven pregnancies with five living children. The pregnancies had evidently alternated in the halves of the uterus.

105. **Intussusception in Children.**—Barth became convinced in 1902 that he had overlooked some cases of intussusception, and since then he has been on the lookout for it in every small child brought to him on account of gastro-intestinal disturbance. He has thus encountered five cases in recent years. In two he succeeded apparently in reducing the invagination but the child died in twenty-four or forty-eight hours. In another case the invagination was of several days' standing and the laparotomy came too late to save the child. Another child had evidently had repeated attacks of invagination which had spontaneously corrected itself. In the latest attack the bowels were flushed with water. Then the invagination was easily corrected through a laparotomy but the child collapsed and died next day, probably from absorption of virulent infectious matter by the damaged mucosa. It is evident that nonoperative measures cannot be counted on after twenty-four hours and, on the other hand, a laparotomy gives the best results when done within twenty-four hours. Even when the invagination seems to have been corrected, it may merely have slid behind the liver. Necropsy revealed this in four of Bloch's cases. Or the invagination may have been corrected, but the swollen bowel and mesentery may simulate a tumor. Passage of flatus and stools is the best sign of reduction of the invaginatum, but this does not occur for several hours. Bloch flushes the bowel with water and measures the quantity of water that can be introduced and flows out again. If the intussusception still persists (ileocecal and colon) only from 50 to 500 c.c. will run in, while if the invaginatum has been reduced, up to a liter will flow in and out. This may aid in locating the tumor, as with an invaginatum in the small intestine as much as a liter will run in and out without any change being apparent in the tumor.

109 *Traumatic Lumbago. K. Malling.—p. 1177.
110 *The Coarse Bread Question. M. Hindhede.—p. 1182.

107. **The Blood in Scarlet Fever.**—Baastrup tabulates the hematologic findings in fifteen patients with infectious sore throat; in ten with scarlet fever with the blood examined repeatedly during the whole course of the disease, and in eighty-seven scarlet fever patients whose blood was examined at different times during the disease. It is evident that the pronounced leukocytosis and eosinophilia even from the first will aid in differentiating scarlet fever from infectious sore throat. Leukocytosis with very few or no eosinophil cells, turns the scale in favor of simple angina. After defervescence, the combination of leukocytosis and eosinophilia will permit the retrospective diagnosis of scarlet fever. Neither alone is decisive, but the presumption still is in favor of scarlet fever.

109. **Traumatic Lumbago.**—Malling warns against casual remarks which may sow the seed of a traumatic neurosis. He admonishes further that roentgen examination may clear up these cases surprisingly. In some cases described this revealed actual injury of a vertebra. In three of the cases there was history of an external trauma; the pain had developed after lifting a heavy weight or slipping on ice.

110. **The Coarse Bread Question.**—Hindhede replies to Leersum and other critics of his publications on the assimilation of coarse bread. A number of them have been summarized in these columns during the last two years.

INSANITY VERSUS MENTAL DISEASES

THE DUTY OF THE GENERAL PRACTITIONER IN PSYCHIATRIC DIAGNOSIS [*]

E. E. SOUTHARD, M.D.
BOSTON

The time has come when the general practitioner must assume responsibilities new to him: he must become as much a psychiatrist as he is specialist in other directions.[1] But how specialistic, it may be asked, is the general doctor-man to be? *Quien sabe?* And times change. But so much is certain: The general doctor-man does not know as much about psychiatry either as he should know, or as he has command of, let us say, pediatrics, gynecology or dermatology. Science, C. S. Peirce defined, I believe, as the range of ignorance. Well, the general practitioner's range of ignorance *re* psychiatry is altogether too wide for his own conscience's comfort and disastrously wide for the good of society.

All this can now be shouted from housetops by reason of what the layman terms "shell shock," a problem for medicine no less wide than the whole of clinical neurology and psychiatry, the field we are coming to know as neuropsychiatry.[2] But already before the shell shock alarums, the American general practitioner had become responsible in these matters for more than his father had to be. In 1906 the state of Michigan had laid down its psychopathic ward at Ann Arbor and placed in control of it a specialist novel in training, functions and scope. Now, it is safe to say, no state can hold up its head in a place of the highest honor in civilization without establishing a psychopathic hospital. The commonwealth of Massachusetts, in 1912, followed the lead of Michigan. Private endowment allowed in 1913 the establishment in Maryland of another institution in which the scientific point of view made use of physicians, psychologists and trained lay workers for the high modern purposes of mental hygiene. Meantime, societies for mental hygiene had been established,[3] and doubtless others are now moving. The yeast is working, too, in the National Conference of Social Work; and just as "charities and correction" has fused and crystallized into "social work," so the former committee of that body on "feeblemindedness and insanity" has now crystallized into a committee on "mental hygiene." The medical man who does not some year attend a meeting of the National Conference of Social Work[4] will sooner or later wake up to reckon without his host—the social worker. In brief, no sign fails to point to an increasing demand for more medical service, as well as for more service of every technical sort, for the psychopath.

But what exactly ought the general practitioner to do for his instruction in modern psychiatry? He looks back at a meager training. He was by law as a rule excluded for a period of years from whetting his mind on medicolegal problems of commitment: the law somehow permitted him to remove an appendix the moment he passed his state board examination, but the law required experience and a partner in the matter of certifying insanity. Again, early in this century a flood of Teutonic verbiage overflowed the field, and the graduate doctor who ventured inside an asylum hastily beat a retreat when *Merkfähigkeit* raised up its head or *Dämmerzustand* closed down over all. Of course various clearly written books gave the main facts (de Fursac,[5] Dercum,[6] Diefendorf,[7] Peterson,[8] White,[9] et al.); but there was little in the medical school memories of most men to tie these facts to, except a few *curiosa* of dismal asylum walks and some medicolegal stories too mature for the nonsocialized medical student to grasp in their proper relations. Am I painting this picture too dark? Now and then at the apex of a particular career some outstanding man is able to prevail on medical colleagues to give him enough curricular time to do the topic justice; but on the whole, even in so-called Class A medical schools, either the ignorance of committees, or curricular pressure, or remoteness of clinical material, or an overripe professional point of view, has killed in embryo the medical student's chances of learning much about psychiatry.

I consider and propose that all general practitioners who feel at a loss how practically to use the relics of their psychiatric training or the products of their reading in such books as the above mentioned should as soon as possible spend at least a week in contact with the clinical material of some institution like the Ann Arbor Psychopathic Ward, the Boston Psychopathic Hospital, or the Henry Phipps Psychiatric Clinic at Baltimore. I specify these institutions, not because the state institution men are unable to give in some instances even more valuable instruction, but because the specified institutions have contact with the acute, curable, incipient and dubious cases that most resemble the most important psychiatric material of general practice. I have not the slightest doubt that the authorities of the specified institutions would not only tolerate but actually welcome the arrival of the general practitioners for such study purposes. I am sure that the general practitioner who comes for a week will want to stay a month and will certainly come back for more.

---

WHAT THE GENERAL PRACTITIONER SHOULD KNOW OF PSYCHIATRY

I want now to sketch the main features of the psychiatric landscape as I think it should be commanded by the general practitioner.

First, the general practitioner ought to become something of a *psychiatrist* and not in the first instance try to become an *alienist*. I am here making a somewhat unfamiliar distinction. In Table 1 I summarize in parallel columns the line of distinction as I think it might well be drawn.

I recently discussed somewhat fully the intricacies of the foregoing parallel column.[10] The point here rather is to ask how much of the field of mental disease, medically considered, the general practitioner ought to have in his range. I suppose there can be no doubt that the general practitioner ought to know relatively as much about psychiatry as he does about the sixteen or seventeen other main groups of topics that we denominate practical specialties. A general practitioner must be *general* in that he has actually more command of all the specialties than any one of the specialists is likely to have concerning the same topics. The general practitioner must at least have the function of being able to specify the right specialist or specialists to call in consultation. If by chance the general practitioner is himself something of a specialist in pediatrics or certain aspects of internal diseases (and surely every general practitioner ought to be something of a specialist in some direction if only to gauge his knowledge concerning general medicine), it is so much the better for the fate of the particular child or adult whose illness is in question. But we do not demand of the general practitioner a fine capacity in the diagnosis of skin diseases or of the minutiae of ophthalmology and otology. Up to recent times, we have not demanded from the general practitioner a knowledge of so much about mental diseases as we have often been able to demand for diseases of the skin, the ear or the eye. The time has come when the general practitioner must assume responsibility in this direction. Even at the expense of postgraduate work on the topic, the general practitioner is going to fail who does not proceed to acquire a grasp on the main conceptions of psychiatry.

TABLE 1.—LINE OF DISTINCTION BETWEEN ALIENIST AND PSYCHIATRIST

ALIENISTS	PSYCHIATRISTS
Field: insanity, the insane	Field: psychiatry, the mentally diseased.
Field: public, governmental, legal	Field: social, private, medical.
Field: *opinion for court* use	Field: medical, psychologic and social diagnosis and treatment.
Decisions *alternative:* Sanity versus insanity	Decisions selective: e. g., syphilitic, feebleminded, epileptic, alcoholic, coarse brain disease, symptomatic, senescent-senile, schizophrenic, cyclothymic, psychoneurotic, etc.
Insanity implies mental disease	Sanity consistent with mental disease of mild degree or of special type
Sanity : Insanity = 1 : 0	Mental disease of *all* degrees, of many kinds

I have recently, for the purpose of discussion with specialistic colleagues, gone over the textbooks and the main classifications used in institutions for the insane and the psychopathic, confining my attention to American views.[11] I find an extraordinary unanimity on the part of these colleagues on the subject-matter of psychiatry. Those of the general practitioners who occasionally dip into the specialistic literature of mental and nervous disease strike into an atmosphere of what must seem the most lively controversy. But in point of fact the battles are greatly localized—I mean the actual battles concerning facts. There is a good deal of nomenclatural difference still preserved in sundry textbooks. I have been trying to put some order into this matter and offer in Table 2 a list of the major groups of mental disease which I think will be found approved by the vast majority of specialists.[12] In fact, I do not know a single specialist who would not agree that in some sense each of the subjoined groups exists. To be sure, some specialists might want to split the groups up further, but of the existence of this mass of medical data there is really no doubt.

TABLE 2.—MENTAL DISEASE GROUPS (ORDERS)

1. Syphilitic	*Syphilopsychoses*
2. Feebleminded	Hypophrenoses
3. Epileptic	Epileptoses
4. Alcoholic, drug, poison	Pharmacopsychoses
5. Focal brain ("organic," arteriosclerotic)	Encephalopsychoses
6. Bodily disease ("symptomatic")	Somatopsychoses
7. Senescent, senile	Geriopsychoses
8. Dementia praecox, paraphrenic	Schizophrenoses
9. Manic-depressive, cyclothymic	Cyclothymoses
10. Hysteric, psychasthenic, neurasthenic	Psychoneuroses
11. Psychopathic, paranoiac, et al	Psychopathoses

I put into the left-hand column the everyday terms for these groups and in the right-hand column a revised and Hellenized nomenclature which I believe has some worth. Concerning this Hellenized nomenclature, I wish to say that in practice I would no more speak of the hypophrenoses in a school for the feebleminded than I would of the *Leguminosae* for dinner or the *Rosaceae* for a nosegay. The advantage of the Grecian nomenclature is quite another, namely, the possibility of exact definition, which the everyday terms do not admit, particularly as some of them deal with disease entities (as dementia praecox) rather than with disease entity *groups*.

The practical contacts of the Boston Psychopathic Hospital with the Massachusetts profession lead me to the idea that the "range of ignorance" of psychiatry by the general profession can safely be localized.

Let us dismiss the eleventh or psychopathic group of the foregoing list, namely, a group I am sometimes tempted to call the "ragbag" group of mental diseases, since the psychopathias, monomanias, psychopathic personalities, etc., which, with varying nomenclature, are dropped into this group, are the regions of densest ignorance on the part not only of general practitioners, but also on the part of psychiatrists themselves.

---

[11] Southard, E. E.: Recent American Classifications of Mental Diseases (to be published in Tr. Am. Med. Psychol. Assn., 1918).

[12] Southard, E. E.: A Key to the Practical Grouping of Mental Diseases, Jour. Nerv. and Ment. Dis., 1918, **47**, 1.

Limiting consideration, then, to the ten other and better defined groups, I note that the first seven are groups whose general features are well enough understood by the general practitioner, so that, barring mistakes in diagnosis and delays in handling, there is a minimum of gross error on the part of the general practitioner.

The general practitioner may not agree, nor will perhaps all of the older psychiatric specialists agree, that virtually every, if not every,[13] case of mental disease requires consideration as possibly syphilitic (I). Nevertheless all practitioners concede that there is a syphilitic group of mental disorders, some of which require intensive treatment.

Again, with respect to the hypophrenias,[14] most physicians are aware of the increasing part played by the diagnosis of feeblemindedness (II) in modern work touching general practice with special reference to the schools and juvenile courts. Though they may be in doubt concerning the exact value and scope of mental tests, nevertheless the general rubric of feeblemindedness has become familiar. So much emphasis has been laid on the higher grades of so-called feeblemindedness, namely, on the "stupids" or subnormals whom it seems invidious to term "feebleminded," that I have had no hesitation in proposing the term "hypophrenic" to cover all forms of feeblemindedness, not merely the feebleminded proper of English and Canadian usage, but also the imbeciles and idiots below the feebleminded proper and the "stupids" or subnormals above the feebleminded proper.

The epileptic group (III) and the group of mental diseases due to alcohol, drugs and poisons (IV), are reasonably familiar to the general practitioner; and although a good many bad mistakes may be committed in these groups, yet the percentage of errors committed by psychiatric specialists themselves in the same groups is so high that we should not weep about general practitioners' motes from our own specialistic eyes containing large beams.

The fifth group in the foregoing classification, namely, that of mental disease due to focal brain disorder (V), is another group sufficiently familiar to the general practitioner, as also to the neurologist whose special field it touches, and the common categories of mental symptoms found therein are likewise familiar. The general practitioner sees enough cases of arteriosclerotic brain disease, of meningitis, of brain tumor and the like, to be familiar with the not very special mental effects that these brain disorders evoke.

Again, in his everyday capacity as a diagnostician, the general practitioner gets a certain familiarity with the sixth or internist's group of mental disorders—the so-called symptomatic psychoses based on definite somatic disorder (VI), such as a typhoid fever, a pneumonia, a puerperal exhaustion, a cardiorenal disease, a dysthyroidism or even a pellagra. The symptoms here also are such as are familiar to the general practitioner and run on the same lines as the symptoms of disease in general.

The seventh, the senile and presenile group (VII), is again a group in which the symptoms are for the most part such as are easy to understand in the quantitative terms of everyday life.

But, with the enumeration of these seven groups, we have come to the conclusion of the list of diseases in which the symptoms are, as one might say, familiar and wellnigh quasinormal, following lines which the physician can readily understand by comparison with the phenomena of his own life. For in the three remaining groups, the schizophrenic (VIII), cyclothymic (IX) and psychoneurotic (X) groups, there are phenomena of such supernormal or subnormal degree or of such an abnormal and dissociative nature that a considerable specialistic study is required to unravel them. I find that many practitioners, even in haughty old Massachusetts, figuratively throw up their hands when asked to define dementia praecox (here termed schizophrenic) or manic-depressive (here termed cyclothymic) psychosis.

As for the psychoneuroses, the attitude of some practitioners, though I hope not too many, is that the symptoms in this group are "imaginary" and by consequence in some sense nonexistent. The attitude of many general practitioners to the psychoneuroses is like the attitude of the Christian scientists to disease in general: the psychoneuroses are regarded as a form, not perhaps of "mortal error," but of nonexistent disease which the patient is to be got rid of by a process akin to exorcism. This erroneous opinion[15] depends on a confusion between the method of psychotherapy and the nature of the etiologic or genetic features of the psychoneuroses. Because by faith mountains are moved, one has no license to consider that faith established the mountains in the first place.

Accordingly, the difficulties of the general practitioner in confronting the schizophrenics and cyclothymics on the one hand, and the psychoneurotics on the other, are of different sorts. The practitioner of some years' standing has simply had no opportunity to study intensively in the medical school or in postgraduate work enough schizophrenics and cyclothymics to permit his understanding their nature. As for the psychoneurotics (whether in the form of hysterics, neurasthenics or psychasthenics), the general practitioner is sufficiently familiar with their general nature, having enough of them and to spare in his consulting rooms. Nevertheless, his ideas concerning them are apt, I think, to be somewhat vague, or at least vague enough to permit his calling many a case of schizophrenia or of cyclothymia erroneously a case of psychoneurosis. Hence I think are brought about a number of false prognoses and a number of poor prescriptions for sanatorium treatment, treatment by change of environment, or special treatment at home, when some other of these treatments than the one chosen would have been far better for the patient.

It is for no academic reason, therefore, that I ask the general practitioner to bring himself up level with the times in the matter of schizophrenia and cyclothymia. I feel that if he gets an adequate notion of schizophrenia and cyclothymia, his already reasonably correct notions of the psychoneuroses will get their proper balance and perspective alongside the other psychoses. I found one really eminent practitioner denouncing the word "schizophrenia" because he had been practicing for decades and ought really to have known what schizophrenia meant if there really was any such symptom or condition. On inquiry, however, I found that the eminence of this practitioner, which was very genuine, had been attained in ways which excluded him from any knowledge of the peculiar symptom or condition known as schizophrenia. And what holds for dementia praecox holds also for manic-depressive psychosis. The week's excursion to some psychopathic hospital or psychiatric clinic, above suggested, ought to lay hold especially on the concepts of schizophrenia and cyclothymia; and the attainment of elementary knowledge concerning these two groups will bring the level of the general practitioner's knowledge concerning mental diseases up to the level of his general knowledge concerning the diseases of other specialties. In particular, his practice with the early cases, cases which he sees often earlier than does the psychopathic hospital or the psychiatric clinic, will be tremendously benefited thereby, and his efforts at psychotherapy will not be measurably wasted on schizophrenics and cyclothymics, but will be concentrated on the genuine psychoneurotics.

[13] Southard, E. E., and Solomon, H. C.: Neurosyphilis: Modern Systematic Diagnosis and Treatment, Presented in One Hundred and Thirty-Seven Case Histories, Boston, W. M. Leonard, 1917.

[14] For this term see remarks by the writer in Tr. Am. Assn. for the Study of the Feebleminded, 1918.

[15] Southard, E. E.: *Shell Shock and After*, Boston Med. and Surg. Jour., 1918, 1-19, especially pp. 76 and 77.

If one thinks that this program for bringing up the level of the general practitioner's knowledge in mental disease to his general level in other specialties is too dogmatic and concrete a program, I have only to say that it is at all events a program, and that measures of some sort are stringently necessary in the interest of the mental hygiene of the community.

I trust that in the foregoing paragraphs I have successfully conveyed the impression that these counsels have nothing to do with nomenclature and terminology, but only with the groups themselves under whatever name they might go. I recently gave a talk on shell shock with some literary examples of the neuroses in the group, and was assured afterward by a practitioner that he was now certain of what he had long suspected, namely, that there was no such thing as shell shock. I found that (*a*) his idea that there was no such thing as shell shock reduced to the idea that had been for some decades in his mind that (*b*) neuroses do not exist because (*c*) their symptoms were "imaginary" and that (*d*) to be imaginary meant for this man to be nonexistent. Now *is or is not this distinction between the imaginary and the nonexistent too fine a distinction to implant in the medical student's mind?* Just as the laity is unable to distinguish successfully between "hereditary" and "congenital," so I find many a medical man unable to distinguish between "imaginary" and "nonexistent." If the neuroses have no structural sign postmortem, are the neuroses nonexistent? But peace to the soul of the general practitioner who listened to my shell shock talk! Calmly identifying "imaginary" with "nonexistent," he probably is a very good psychotherapeutist among his parochial flock.

I have adverted above to one little matter of nomenclature, insisting on the virtues of the term "hypophrenic" as including the entire swelling group of the so-called feebleminded. The human advantages of using the term "hypophrenic" pale into insignificance beside the advantages of using some other term for the so-called dementia praecox group than the term borrowed by Kraepelin to designate a group of diseases which he had synthesized from the literature. Some day I wish to write a paper called "Nondementia, Nonpraecox."

If I tell a layman that so-and-so is suffering from shell shock, the layman is aware that the term "shell shock" *connotes* a great deal about the war and its effects, but quickly observes that the term *denotes* little or nothing, and he is forthwith thrown back on the expert for information as to what shell shock really means and what its prognosis may be. Not so when the ardent social worker learns that so-and-so is a victim of dementia praecox. Is she not almost entitled to think that a victim of dementia is demented or else is going to become demented? Are there not similar significances attached to the term "praecox"?

I believe that a great deal of harm has come to patients from the use of the term "dementia praecox," and most psychiatric specialists whom I have consulted on the point cordially agree with me. On this account I have felt that the proposal of the Swiss psychiatrist Bleuler[16] to use the term "schizophrenia" for cases subject to the peculiar dissociation found in these cases is a good one. The fact that it has a peculiar sound, novel to medical ears of the last generation, is no good reason for denouncing the term "schizophrenia," since the symptoms of the disease are at least as peculiar as the name, and there is a good deal of novelty about the whole conception to many general practitioners and consulting internists.

I will not here argue in detail for the use of the term "cyclothymia" instead of manic-depressive psychosis, although I think the tendency of usage and certain logical points may be advanced in favor of cyclothymia, a term which includes in its prototheme the idea of periodicity, always potential in this disease, and in its deuterotheme the idea of affective or emotional disorder, a constant feature of the disease.

I give below the subforms of these eleven great groups of mental disease.[17] These subforms are a product of some American textbooks and specimens of classification now most in vogue. I think this listing, for which I do not wish here to argue in detail, certainly shows that psychiatry is on a pretty stable basis so far as classification is concerned—possibly as stable as many other growing specialties.

Two points are to be made concerning this subjoined list. The diagnosis of these entities (or generic groups) under the greater groups (or orders) is not to be expected of the general practitioner, nor even of the psychiatric specialist on cursory or brief examination. Indeed, I hold that much harm has been wrought by an offhand diagnosis of "general paresis" when all any one could really say, with laboratory tests also in hand, was that the patient had "neurosyphilis." Many errors of this sort, both by general practitioners and by psychiatrists (including ourselves), are given in detail in the monograph published by Solomon and myself[13] in 1917 on neurosyphilis. No, it is much better for the peace of mind of practitioner and patient that the practitioner shall stop short with his *group* diagnosis and let the *entitative* (generic) diagnosis wait on the psychiatric specialists (one of the soundest of whom is Father Time). It is not for the purposes of "brilliant," that is to say, premature and at all events merely lucky, diagnoses that I subjoin the genera which American psychiatry seems, by its textbooks, to afford.

---

[16] Bleuler: Schizophrenie, in Aschaffenburg's Handbuch der Psychiatrie, 1911.

[17] For more particulars, see *Southard, E. E.*: The Genera in *Certain* Great Groups of Mental Diseases, to be published in *Tr. Am. Neurol. Assn.*

The second point deals not with the objects of diagnosis so much as with the process of diagnosis. I have placed the great groups with Roman numerals (I, Syphilopsychoses; II, Hypophrenoses, etc.) in a certain sequence which I take to be the practical sequence of successive exclusion and elimination that is of the most value in the present phase of psychiatric theory. No one need use this sequence if one prefers another, and the sequence will inevitably change in the course of time when new facts and new tests are granted to us. And not only the sequence but also the list itself will inevitably alter. Not only have I placed the greater groups or orders of mental disease in a particular practical sequence, but I have endeavored also to place the smaller groups or "genera" of mental disease in a practical diagnostic sequence under each greater group. Again, any one who chooses to use the items as a *list* and not as a *sequence* is entitled to do so: I would claim only that *some* sequence is of practical value in diagnosis, at least for tyros.

TABULATED SUGGESTIONS FOR GENERIC CLASSIFICATION OF MENTAL DISEASE GROUPS

I. SYPHILOPSYCHOSES (the syphilitic mental diseases):
Genera:
General paresis
Juvenile paresis
Nonparetic forms:
Meningitic
Vascular
Gummatous
Less common genera:
Syphilitic feeblemindedness
Syphilitic epilepsy
Tabetic psychosis[18]
Syphilitic paranoia
Atypical

II. HYPOPHRENOSES (the feeblemindednesses, including graded forms of idocy, imbecility, moronity (in the English nomenclature feeblemindedness proper) and subnormals):
[Syphilitic[19]]
Encephalopathic:
Microcephaly, hydrocephalus, focal brain disorder
Glandular:
Cretinism, infantilism, dysadenoidism, mongolism (?)
Hereditary:
Feeblemindedness, amaurotic family idiocy
Atypical

III. EPILEPTOSES (the epileptic group):
[Syphilitic[20]]
[Feeblemindedness with epilepsy[21]]
Alcoholic
Traumatic
Encephalopathic
Jacksonian
Symptomatic
Idiopathic
Equivalent
Narcoleptic
Borderland

IV. PHARMACOPSYCHOSES (the group of mental diseases due to alcohol, drugs and poisons):
[Epileptic[22]]
Alcoholic:
A. Pseudonormal:
Drunkenness, pathologic intoxication, dipsomania
B. Peripheral—Central[23]
Delirium tremens, hallucinosis, Korsakow's disease, pseudoparesis
C. Central
Jealousy-psychosis, paranoia (?), dementia
Drug:
Morphin, cocain, alkaloid
Poison:
Lead, gas, mercuric chlorid, special

V. ENCEPHALOPSYCHOSES (focal brain lesion group of mental diseases):
[Syphilis[24]]
[Feeblemindedness[24]]
[Epilepsy[24]]
[Alcohol, gas[24]]
Traumatic. Note that the traumatic *neuroses*, although they form a group of mental diseases, belong not here in Group V, but below in Group X, the psychoneuroses.
Infectious. The infectious group of encephalopsychoses here listed refers to cases like brain abscess and meningitis in which the organism has produced local destructive effects in the brain.
Neoplastic
Vascular. Under this group would fall the great group of arteriosclerotic dementias which, be it noted, are parted out from the old age psychoses, Group VIII, below.
Degenerative

VI. SOMATOPSYCHOSES[25] (the so-called symptomatic group of mental diseases):
[Glandular feeblemindedness]
[Symptomatic epilepsy]
Infectious, e. g., typhoid
Exhaustive, e. g., puerperal
Metabolic, e. g., cardiorenal
Glandular, e. g., thyrotoxic
Pellagrous

VII. GERIOPSYCHOSES[26] (the presenile-senile group of mental diseases):
[Epilepsy]
[Vascular]
[Alzheimer's]
[Progeria]
[Late catatonia]
[Involution melancholia]
Presenile psychosis
Senile dementia
Presbyophrenia
Senile psychoses

VIII. SCHIZOPHRENOSES (the dementia praecox group):
Hebephrenia
Catatonia
Paranoid
Cyclothymoid[27]
Schizophasia
Dementia praecocissima
Dementia simplex
Paraphrenia

IX. CYCLOTHYMOSES (the manic-depressive and cyclothymic group of mental diseases):
Cyclothymic constitution
Manic-depressive[28]
Melancholia
Mania
Mixed[28]
Involution-melancholia

X. PSYCHONEUROSES:
Hysteria
Neurasthenia
Psychasthenia

XI. PSYCHOPATHOSES (the psychopathic group of mental diseases):
Prison psychosis
Folie à deux
Litigation psychosis
Paranoia
Sense deprivation psychosis
Monomania
Psychopathia sexualis
Psychopathic personality

SUMMARY

The psychiatrist is a specialist in a very complicated field with numerous great groups of diseases for his diagnostic consideration. Each of these great groups is likely to be as complicated within itself as, for example, the group of Bright's disease or the exanthems. The psychiatrist is logically opposed to the alienist. The latter has the function of the public and medicolegal adviser, whereas the psychiatrist is a practitioner whose aim is not merely diagnostic with respect to commitment; his aim is diagnostic with respect to a great number of therapeutic possibilities.

---

[18] Of course this is sharply to be distinguished from ordinary tabes dorsalis and nervous disease, and from so-called taboparesis, which by the best nomenclature is a subform of general paresis.

[19] Syphilitic feeblemindedness has been classified under the syphilopsychoses, Group I.

[20] These have been classified under the [illegible] I.

[21] These have been classified under the [illegible] II.

[22] These have been classified under the [illegible]

[23] The nomenclature of these subgenera must remain dubious. I think most workers among the alcoholic psychoses would recognize the value of dividing them in some such triple way as above. The general practitioner has not yet at all clearly in mind, I think, the distinction now drawn by specialists between drunkenness and pathologic intoxication and between delirium tremens and alcoholic hallucinosis. Perhaps it would be well enough to leave these distinctions to the specialists were it not for the fact that so many medicolegal points hinge on the practical decision in cases that fall into the hands of the police.

[24] These have been classified, respectively, under syphilopsychoses, Group I; hypophrenoses, Group II; epileptoses, Group III, and pharmacopsychoses, Group IV.

[25] The term "somatic" is here used following a frequent neurologic plan which employs the term "soma" for the body at large, as against the "encephalon" or brain.

[26] This term is adopted provisionally as against the possible term "presbyopsychoses" because of Nascher's choice of the term "geriatrics" for his proposed branch of medicine, dealing with the diseases of old age.

[27] This genus, if it be such, is devised to include a practically very important group of cases in which the schizophrenic process is precipitated by phenomena that resemble manic-depressive psychosis, or in which there is a definitely cyclothymic course in itself suggesting the true cyclothymoses.

[28] These two forms are designed to include, respectively, cases in which phases of pure mania of depression follow one another, and the cases in which depression and maniacal phenomena are commingled within the single phase.

The general practitioner must now advance to at least as much responsibility in psychiatry as he has in pediatrics, gynecology or dermatology. The general practitioner, if he is to remain of value, ought to know more about all the specialties than each specialist would be apt to know about all other specialties than his own.

Recent reviews of the ideas of psychiatric specialists show a great deal of unanimity as to the major groups of mental diseases. This genuine unanimity is obscured by nomenclatural divergence. At the risk of increasing the nomenclatural divergence, I have been of late proposing a pragmatic key to the group of mental diseases, dividing up the groups according to general and special therapeutic possibilities. I have accordingly no etiologic or somatosystematic suggestions to offer. My classification is purely practical and has no relation either to obvious clinical units from the standpoint of observation or to anatomic resemblances. For example, I would contend that a grouping of mental depressions as sometimes syphilitic, sometimes cyclothymic, sometimes symptomatic, etc., gives the practitioner no orderly means of making his decision in a brief space of time. Such a classification on the ground of clinical resemblances is, in office practice, next to useless, whereas the bigger decision as to whether the patient probably belongs in one of the eleven groups as herein presented is practically much more valuable. Then if the quest can be localized to two or three of the eleven groups, the patient's fate will be greatly benefited.

Again, I feel that the classification of certain diseases as organic dementias hurts the outcome for the patient by delaying decision. The practitioner is rather apt to feel satisfied with thinking that a case is somehow organic, whereas it may be his immediate duty to settle once for all whether the patient is syphilitic, and then to proceed to the more careful differentiation of the possibilities in the focal brain lesion group. But my attitude in general with respect to the general practitioner's duties in diagnosis is that in the first place it is his duty to determine whether the case belongs in the mental group and then to proceed to answer as many questions as available ordinary clinical tests can answer with respect to the place of the patient in some one of these major groups. It is certainly a waste of time for the general practitioner to approach the neurologic specialist with an at all complicated or longstanding case in which the serum test for syphilis has not been performed. With the multiplication of opportunities for mental tests, it is also a waste of time for the general practitioner not to have submitted his case to such tests before bringing the patient to the specialist. I do not mean that the general practitioner should himself perform these tests but that he should utilize some local psychologist competent to perform them.

And so through the list, if the general practitioner knows the main features that distinguish these greater groups of mental diseases from one another, he will be able to utilize the specialist to much greater advantage. The specialist who should fear that his practice would be diminished by such a process on the part of the general practitioner would be so foolish that I suspect he could not be an effective specialist; for if the general practitioner could grasp the main features that distinguish these eleven greater groups of mental diseases from one another, he would carry to the specialist scores and hundreds of cases more than he now carries. For under these circumstances, the general practitioner would know how to couch a great many more questions.

Meantime I find from my Boston Psychopathic Hospital practice that the general practitioners are pretty well grounded in the first seven of the major groups of diseases listed. The general practitioner also has certain ideas concerning the psychoneuroses, but is rather apt to make somewhat obvious errors in the field of the schizophrenias (dementia praecox) and the cyclothymias (manic-depressive group). Sundry patients suffer therapeutically on account of delayed diagnosis in the two latter groups and especially from an erroneous identification of them as belonging to the group of the psychoneuroses.

As for the psychopathias in general, the general practitioner need not rush in where the psychiatric specialists fear to tread.

CONCLUSIONS

1. The advance of the mental hygiene movement throws more responsibilities in psychiatric diagnosis on the general practitioner.

2. The general practitioner should bring his specialistic knowledge of psychiatry up level with his specialistic knowledge, in ophthalmology and dermatology, for example.

3. Alienists are to be distinguished from psychiatrists, and forensic psychiatry ("alienistics") from practical psychiatry, in certain ways (Table 1).

4. There is at present great unanimity on the part of American specialists in mental disease, as indicated by the adoption of common statistical forms (American Medico-Psychological Association).

5. For arriving at a diagnosis of mental disease, I suggest an arbitrary order of exclusion by eleven great groups, into which I have thrown the accepted entities.

6. Nomenclatural divergences are much more frequent than divergences on facts.

7. The use of Bleuler's term "schizophrenia" for dementia praecox and of the term (in cognate use) "cyclothymia" for manic-depressive psychosis is advocated in the line of exactitude and the ready formation of adjectives and relative terms.

8. The use of a new term "hypophrenia" for the various feeblemindednesses is advocated.

9. The ending "osis" is in general advocated for the larger groups of mental diseases, parallel with the use of "aceae" and "osae" for botanical orders.

10. A tentative list of "genera" under these orders is given in the text.

Baking Bread with Waste Heat.—The city council of Reykjavik, Iceland, has begun the experiment of baking bread in a special bakery which utilizes the waste heat from the local gas works. The result has been excellent and in a short time, according to a report of Consul B. L. Agerton at Copenhagen, *Commerce Reports*, Sept. 17, 1918, all the black bread which may be needed will be baked in the new bakery. This is thought to be the first experiment in bread baking by waste heat.

CEREBRAL EDEMA FROM PRESSURE *

W. A. JONES, M.D.
MINNEAPOLIS

The title of this paper may not be entirely in keeping with the contents, but it is intended to open the subject of localized cerebral edema from various causes, particularly from pressure conditions, and also to bring out similar cases, recorded or observed by members of this section, in which focal symptoms suggest a more extensive lesion of the brain which, if operated on, shows that a simple edematous state presents itself, after which the symptoms subside, leaving the diagnosis either a speculative one or one which may be properly termed a localized cerebral edema.

General cerebral edema is undoubtedly a frequent accompaniment of many of the somatic disorders. The most common, probably, is a chronic nephritis or the triad of heart, kidneys and blood vessels. These diseases of the circulatory and eliminatory systems are very commonly associated with stupor, convulsions and neuroretinal lesions and papilledemas. When such a combination of symptoms occurs, it is reasonably fair to assume that the mobility of the cerebrospinal fluid has been altered perhaps on account of a change in the circulatory system within the cranial box. When one considers the relation of the arachnoid and the pia to the fluid contents of the skull, it is easy to hypothecate a probable edema of the membranes or of the cortex itself. Then, too, we have learned that tension of the occupied spaces in the head, either from tumors or thickenings, not infrequently tend to crowd the brain into the foramen magnum; and this in itself is quite explanatory of an edematous state, either peripheral or central.

The delicate tissue strands, which bind the pia and the arachnoid together with the perivascular spaces through which the fluids of the brain circulate, may easily become altered, because it is known that the cerebrospinal fluid, although it is partly protective and offers itself as a water bed to the brain, is intimately connected with the venous circulation through small rudimentary sinuses. Moreover, the cranial nerves themselves, notably the first and second, surrounded as they are by perivascular spaces and delicate tissues, offer a convenient outlet for some of the cerebral fluid contents, although most of the fluids escape into the sinuses, whether large or small. One can readily imagine that a general or local infection of any kind which blocks the venous channels may easily lead to an edematous local condition, such as occurs in thrombosis of the longitudinal sinuses or in a congenitally and badly constructed drainage system in the brain, whereby an old hydrocephalus is either lighted up or is followed by a local or a general cerebral edema.

THEORIES OF EDEMA OF THE BRAIN

E. M. Baehr[1] discusses edema of the brain from a general, as well as a local symptom group, and advances with others the theory that coma, from whatever toxic agent, presents its symptoms through cerebral edema, local or general.

Tauber's theory adds to this a probable acidosis, and incidentally states that these edematous cerebral conditions are not relieved for any length of time by injections of alkalines, as this method is usually a failure on account of the blockade of the cerebral blood stream. Then, too, we have the kidney theory in which the theorist believes that a toxin has developed, but where, when, or how no one knows, although Baehr advances the idea that some toxin developing from the kidney condition may be responsible for a cerebral edema. Baehr asserts, further, that there are four groups of symptoms that occur and are diagnostic of cerebral edema: first, an altered mental state in which the patient varies from a noisy state to one of moroseness; second, a state in which convulsions develop, sometimes accompanied by paralysis, but this is usually temporary. The third group consists of those which come under the heading of comas, and the fourth group in which there is impairment of the functions of the medulla, a poor mechanical condition, accompanied by dyspnea, disorders of the heart rhythm and occasional vomiting and diarrhea.

Mills, in his book, "The Nervous System and Its Diseases," devotes a short section to edema of the brain, and says that in former years it was customary to discuss edema as a separate disease, but that in recent years the tendency has been to consider it only in connection with those systemic diseases and focal disturbances of which it is a feature. Preston, from whom Mills quotes, concludes that among other things edema should receive recognition both from a clinical and a pathologic standpoint; that, although it follows the laws of edema elsewhere in the body, it is considerably modified by the anatomic lymph spaces of the brain and its membranes; that the effused serum may exert mechanical pressure and offer occasion for toxic influences; and that it would be a more common and serious affection, were it not for the free communication which exists between the various lymph spaces as shown by the decided symptoms produced when these cavities are isolated by inflammatory adhesions. Mills mentions, also, that edema of the brain may be partial or general, acute or chronic, and that when it is locally present it is usually due to a local inflammation or pressure from a focal lesion, such as a tumor or an aneurysm. Now that infections have occupied a very large place in our diagnostic outlook, it is even more probable that localized edemas may occur and be followed by a fairly well defined chain of symptoms which resemble in type the symptoms due to the pressure of diseased areas or growths of various kinds. Then, too, in studying the question of fractures, injuries to the head, we find that the penetration wounds, which occur sometimes in such minute forms as to escape detection, may in turn produce a local edema followed by an infection and a breaking down of the membranes of the cortex itself. Under such causative states, edema is probably a secondary condition, but not infrequently an edema may occur without these provocations, but be due to some obstacle in the network of the cerebral veins.

In his book, "The Surgery of the Skull and Brain," L. Bathe Rawling refers to edema following injuries associated with the vasomotor depression and accompanied by engorgement of the superficial cerebral veins with an increase of the cerebrospinal fluid and edema both of the pia-arachnoid region and of the brain itself. Even under concussion, localized edemas may arise, due, probably, to the same obstructive or destructive conditions which occur in the veins or perivascular channels. In referring to traumatic neurasthenia, Rawling further defines edematous conditions of the pia-arachnoid and of the cortex,

---

* Read before the Section on Nervous and Mental Diseases at the Sixty-Ninth Annual Session of the American Medical Association, Chicago, June, 1918.

[1] Baehr, E. M.: Lancet-Clinic, 1914, **111**, 696-701.

and in exploratory operations he is particularly impressed by the fact that in a large proportion of cases one finds what appears to be a condition of local edema, some fluid beneath the dura mater, and a greater excess of the same in the pia-arachnoid meshwork, and he says that Leonard Hill's experiments show that edema is dependent on chronic vascular changes, arterial anemia, venous congestion, and cerebrospinal and serous accumulation. Not infrequently an epilepsy has for its focal origin an edema of the membranes and, occasionally, of the cortex. In some of these cases the patients are relieved or cured by a decompression operation. Just so are cases of acute maniacal disorders, and those which follow an accident within a few hours or a few days. The acute cerebral edema is not infrequently present and due to a severe grade of vasomotor depression; it is occasionally, although not always, preceded by a cerebral injury. Some of the patients who have been operated on for supposed cortical or subcortical growths show, on removal of the bone and resection of the dura, that cloudiness only is present. The condition of such patients may clear up immediately after the operation, with a clinical or actual recovery, due to the relief of conditions which have produced pressure and temporary or transient edema.

REPORT OF CASES

Case 1.—W. L. was admitted to hospital Jan. 5, 1917, with a negative family history. His father, a vigorous Scotchman, is still living. There had been no deaths in the family except that of his mother, who died in early life of pneumonia. There is no history of nervous or mental disorder. He had had some of the diseases of childhood, but never was seriously ill. He denied any venereal contagion, and none was evident by examination. Although a man, aged 30, he had been singularly quiet in his habits, rather more so than is necessary for the average growing individual. In fact, most of his social life had been in the neighborhood of the Sunday school, church picnics and things of that order.

The patient, so far as he knew, had been in good health up to Dec. 23, 1916, about two weeks before his admission to the hospital. He was a hard worker in a bank, but somewhat retiring in his disposition, bashful and unwilling to display his activities. He had had neither worry, strain nor disappointment to contend with, nor any physical disease that he could recall.

December 23, he suddenly realized that his left arm and hand felt queer, as he expressed it—a numb sensation, as if the limb had been cold. This occurred during a busy hour, and he paid very little attention to it. The following two or three days, during which Christmas intervened, he went to work, and soon found that his left hand was clumsy, and he had difficulty in executing the finer movements. He went to a physician, who advised massage, but gradually the limb grew worse, and the left leg became involved, until he was obliged to go to bed for a few days. He had no rise of temperature, and no special pains except the numbness and an occasional catch in his limbs, arm and leg, on moving them. He had no headache, no visual disturbance, and he was not exposed, so far as he knew, to cold, nor did he have a sore throat. During the night, while on a train coming to Minneapolis, his arm grew very much worse, and he had frequent contracting movements in his fingers, hand, wrist and forearm. When he arrived he was unable to use the hand, and he found it very difficult even to extend his fingers in any way. He had no trouble with his voice, nor was there any involvement of any of the cranial nerves. He remembered that on two occasions in December, 1916, he had had transient dizzy attacks, but he had attached no importance to them, as they had not inconvenienced him for any length of time.

His weight was 135 pounds, and there had been no change in that so far as he knew. His nutrition and general development were fairly good, but he appeared rather pale and worn. The pulse was 92, and blood pressure 98 systolic and 62 diastolic, and there was no thickening of the arteries, but the heart sounds were distant and rather poor in quality. There were no murmurs or apparent failure in his heart muscle. He had a pharyngeal reflex, and his tongue, although slightly coated, was a little tremulous and, he thought, a bit swollen. There was no trouble with his bladder or rectum. His teeth were in fairly good condition. There was engorgement in both fundi, and the disks showed a marked cupping, but no edema was noted. The right pupil was smaller than the left and irregular in outline. The right pupil was practically stationary, while the left showed slight reaction. The movements of the eyeball were capable in all directions, but there was a slight nystagmoid movement on his looking to either side. His motor power was impaired on the left side, involving the arm and, to a lesser degree, the leg. There was a slight tremor in extending the hands. There was incoordination in the left arm, but coordination was good in the left leg. His gait naturally had a hitch in the left leg, but it was not very marked. There were no contractions and no atrophy. There was no loss of tactile sensibility on the paralyzed side, but there was a loss to vibration sense in both leg and arm, and his astereognostic sense was markedly impaired on the left side. Joint sense and heat and cold sense were normal. Both of the deep reflexes were double plus, and the reflexes of his upper extremities in both sides were present, with a little overactivity in the left biceps and triceps. There was an overactivity of the Achilles tendon in each heel. He had no clonus, and his abdominal and cremasteric reflexes were present. He had a Babinski reflex in the left foot.

On the day following his admission he received a spinal puncture, in which the fluid presented a rather cloudy appearance, but without increase in pressure. The examination of blood and spinal fluid was negative. After the puncture he became very faint. His pulse went down to 48, and it was several moments before he revived. The asynergy of the upper left limb was very marked, and he complained of increased sensation and drawing or contraction of the arm muscles.

During the four days following his admission, there was an increase in his symptoms, particularly in the joint sensation in the left arm, which involved fingers, wrist, elbow and shoulder. In the foot joint, sensibility was retained and was apparently normal, but vibration sense was impaired in both leg and arm on the left side. Incoordination had increased on the left side, particularly and notably in the left arm. During the course of the examination it seemed as if the right arm showed slight impairment in coordination, but it was not worthy of consideration.

January 12, the patient was removed to a surgical hospital and was operated on the following day. Before the operation he complained that his eyes were tired, but he had no hemianopia or increase in his hyperemia or enlargement of the fundi. The operation was done over the right posterior, parietal region, and was a large bone flap operation.

After resection of the dura, a localized edematous spot, involving not only the pia-arachnoid but the outer layers of the cortex of the brain, was found. This pia-arachnoid accumulation was easily removed and the membrane scarified. The cortex itself was scarified lightly over a reddish area. During the operation the edematous condition cleared up and left the brain in what seemed to be a normal color and condition.

After the usual few days of postoperative symptoms the patient improved very steadily and rapidly. His motor power was improved, and his general mental attitude resumed its normal phase. His vision cleared and the pupils reacted to accommodation, but did not change much in their outline and were slightly irregular, and four weeks after the operation he was practically well. There was no hitch in his gait, and the movements in the left leg, which had prevoiusly been restricted, resumed a normal tone. His station was good, and there was no Romberg sign. He complained of a slight feeling in his tongue, and there was a slight tremor at the end of two weeks. His general coordination was apparently normal, and the motor power in his left arm was approximately what it is in all right-handed people; that is, the difference between the two was normal. In his sensation he had a restoration of all touch, pain, joint and vibration sense, which showed a very marked change from the condition at the former examinations. His astereognostic sense was normal. The reflexes of the upper extremity were equal on both sides and approximately in a normal condition. Since his operation in January, 1917, he has been heard from on several occasions. He has resumed his work as assistant cashier in a bank and has used his right and left arms with equal facility. In a recent letter he has expressed himself as feeling perfectly well and very anxious to get into Army service; but, on account of his osteoplastic operation and the condition found there, he was discouraged from entering the service.

Case 2.—H. G., aged 25, admitted to the hospital Jan. 6, 1914, was a salesman, whose family history was from all points negative. He had had measles, mumps and erysipelas when a child. The father gave a history that when the boy was 5 months old he was in a runaway and was knocked senseless, but at that time no evidences of fracture or depression of the skull were found. The patient had begun to drink when he was 12 years of age, and had continued his drinking from that time up to the time he was seen in the hospital. When he had been a young boy he had been very difficult to manage and had shown all sorts of tendencies that were more or less of the defective type. Like many other boys, perhaps, he had been guilty of petty thieving from his home and his father, and sometimes would appropriate a horse or motor and go off for a day. During the time when the boy was not drinking he was extremely likeable and very industrious. He always slept well, and there were no evidences of any disorder of mentality after he had passed the age of puberty. There was some reason to suspect that he had a thick skull, although there could be no diagnostic symptoms of this given. The idea was that he was possibly defective, and an examination of his head, after it was shaved, showed some minor depressions over the parietal and occipital region. He was subjected to a double subtemporal decompression. Three days later he had a convulsion, and within a week he ran away from the hospital, but came back willingly and smilingly. From that time on his recovery was rapid. He came under observation again six months later. He came up to the family's standard physically and mentally, and they said that since the operation he had had no desire for alcohol. He later married, and has been well ever since.

Case 3.—E. P., aged 18 years, had a father and mother living. The only history of any moment obtainable was that the paternal grandfather had epilepsy late in life. This boy was well until he arrived at the age of 14, when in a fall he struck on his head. He had been unconscious for an hour, complained of headaches afterward, and was nervous from that time continuously; but when he was able to avoid excitement he did very well up to within a month of his appearance in Minneapolis on Jan. 19, 1912. Then he began to have attacks of unconsciousness, which occurred with great frequency. During these attacks, or after them, he was evidently laboring under some hallucinations or became frenzied so that he threatened to kill people for minor causes. Before coming to Minneapolis he had spent a month in the State Hospital for the Insane at Rochester, Minn., where he had been observed, but was reported unimproved. His family thought he had an indentation of the skull at a point where he struck in falling, but it was not easy to map out, and when he was operated on later there was no evidence of fracture. During his attacks of unconsciousness he resembled the average epileptiform patient, except that there were no movements or frothing at the mouth. But he always complained of a headache and he was inclined to sleep after the attack. In one of his attacks before he went to the state hospital he had wandered off into the fields and had to be returned to the house and watched. The history further brings out the fact that three months after his accident, which was in 1907, he had had a few of the present type of attacks of unconsciousness.

Without any localizng symptoms in view, without any findings in the eyegrounds and without any evidence of any involvement of other cranial nerves, and purely because of the attacks he had, it was assumed that he had a hard skull and that he probably had some pressure symptoms that might be relieved by an operation. He was in a peculiar state of mind —excited, alert and inclined to irritability. All of his reflexes, both superficial and deep, were extremely active.

Jan. 29, 1912, he was operated on. A scalp flap was raised on top of the head with an anterior attachment, and two trephine openings of an inch in diameter were made on either side of the median line, just behind the frontal parietal suture. The skull was very dense and very thick. The openings made by the trephine were enlarged with a rongeur and revealed a thickened dura, which was opened and turned back. The pia-arachnoid showed a cloudy thickening and resembled a cyst between the membranes, but this prevailed in all parts of the opening. These filled areas and edematous places were scarified thoroughly, and the brain was swabbed with 1/1000 mercuric chlorid solution. The dura was left open and tucked under the scalp for permanent drainage. A thorough exploration of both the inside and outside of the dura for two inches around the opening was made, but nothing was discovered in the way of a tumor or any other disease.

Perhaps two of the interesting points about this case were the clearing of the grayish membranes and the relief of the edema when the skull was opened. We watched this process in each opening, and before the operation was completed both of the areas were free from edema and showed the normal pink surface of the cortex.

This man made a quick recovery and has remained free from either attacks or mental disorder ever since.

CONCLUSIONS

1. There are undoubtedly many cases of local or generalized cerebral edema that are unsuspected.

2. Patients who give a history of an injury, however remote, provided it is localized, may have a local cerebral edema from pressure and from a fracture of the internal table of the skull, or from simple concussion of the brain, or a blow on the head, with or without infection.

3. Occasionally cases exhibiting focal symptoms may be wholly due to a localized edema, and too few cases of epilepsy, acute and violent but with transitory mental excitements, justify an exploration for a suspected edema.

4. There are many cases of hard, thick skulls, obstructing free circulation in the pia-arachnoid and in the cortical veins and perivascular spaces, which may be temporarily or permanently relieved by decompression operations.[2]

ABSTRACT OF DISCUSSION

Dr. Frank P. Norbury, Jacksonville, Ill.: I would like to ask Dr. Jones how he excluded the cardiovascular renal states in the first cases reported. I have a case under observation now, and I think it is wholly a cardiorenal condition. Whether we are justified in opening the skull in a cardiorenal case is a question I would like to have answered.

Dr. Andrew L. Skoog, Kansas City: Referring to the point relative to edema causing the focal type of epilepsy, there still remains a certain number of cases with an epileptic syndrome in which we do not know the etiology. It is possible that the edema of the brain is the cause of this disturbance primarily. On the other hand, in a large number of cases of edema of the brain we do not know the cause. Possibly they are due to some obscure intoxication of the cortex, which causes either focal or generalized edema of the brain. In regard to treatment, I see no objection to doing a decompressive operation in some cases. However, I think we are justified in first trying to relieve these patients by removing cerebrospinal fluid, possibly once, possibly two or three times. I have had several of the cases, in which I believe the results were just as good by resorting to such a simple procedure, as might have been obtained if a decompression operation had been performed.

---

[2] Many of the compilations embodied in the first few paragraphs are from Keen's "Surgery" and accredited to Cushing and Bordley, 7, 728.

Dr. Albert E. Sterne, Indianapolis: It depends entirely on what we mean by edema of the brain. We should not use that term unless we mean a cellular encephalitic process, a serous encephalitis. We should distinguish between edema and any form of hydrocephalus. Furthermore, in certain conditions, an encephalitic process frequently arises in the brain no matter what the etiology may be, whether it is traumatism, tumor, infection, exhaustion, sunstroke, or due to a drug or syphilis. Under those conditions the only thing the brain cell can do, primarily, is to swell. This is the preliminary stage of an inflammatory process. Then, if by the term edema of the brain, Dr. Jones means such a process as that, I would subscribe to such a conception. But I do not believe I should consider that edema of the brain arises in a purely local manner. Without doubt there can be intensification of the general swelling in a given territory, but I do not believe it arises in a circumscribed fashion and remains circumscribed.

Dr. Joseph Byrne, New York: I confess to having doubts as to the localization in the first case Dr. Jones reported. There are a few inconsistencies in the sensory manifestations. For instance, motor power and stereognosis were defective in the left hand, but the author did not specify as to these functions in the right hand. I would ask just what the condition was in that respect. If the left hand only was involved, the trouble probably would be in the commissural fibers. The second point is as to the question of vibration. There are two elements in vibration: the affective or thalamic element and the critical or cortical element. These two things should be differentiated sharply. The specific element of heat as such, as well as the element of rapidity in vibration, implies comparison and is to that extent critical or cortical, whereas the pleasant or unpleasant feeling of heat or vibration (affective element) is mediated by the thalamus. The question of edema has not been settled satisfactorily to physiologists. It is the problem of physiologists to-day just as it was many years ago, Dr. Martin Fisher's work to the contrary notwithstanding.

Another question that comes up is the mechanism of cerebral nutrition. I do not want to be overcritical, and it may be merely a play on words, but there are no lymph vessels in the brain tissue or spinal cord. There are perivascular spaces but no lymphatics. Then, another question comes up as to the rôle of a very important structure the function of which has not been defined clearly. The neuroglia is in close anatomic relation with the perivascular spaces on the one hand and with true neural tissue on the other, and hence may play an important rôle in neural nutrition. We are a long way from having a true conception of the mechanisms of cerebral nutrition.

I differ somewhat from Dr. Jones as to diagnosis and localization, although I agree with him as to his method of treatment. Our practical work in cases like this has been most successful. I believe that in all these cases a decompression on one or the other side has great influence in restoring nutrition and function.

Dr. Bayard Holmes, Chicago: I have been interested in the possibility of reducing edema of the brain on account of its occasional appearance as a terminal factor in dementia praecox. When the two cases that were reported by Nissl came out I began to look for some method of reducing the increased intracranial pressure and edema which seemed to be present in those cases, and found that when there was a high intraspinal pressure, which presupposed, perhaps, a high intracranial pressure, it could be reduced by the intravenous injection of large quantities of a concentrated solution of glucose, the concentration being about 33⅓ per cent. or higher. And I wondered whether in such instances as those reported a concentrated solution of glucose might not be useful in reducing edema of the brain, perhaps anticipatory of any surgical interference. In the few instances wherein we used the intravenous injection of a concentrated solution of glucose the intraspinal pressure went down and remained only a short time, not to exceed twenty-four to forty-eight hours, when the intraspinal pressure rose to the high point from which it had come. In most cases we found the pressure to be from 150 to 380 mm. of water, and six hours after injection of the glucose it had fallen, in one case, to 40 and in another to 80 mm.

Dr. William A. Jones, Minneapolis: The discussion has brought out the points I wished to emphasize. I think there is absolute justification in the decompression of many people who have ill-defined conditions in the cortex and meninges, and I believe we will find many localized edemas, from whatever cause. One case of mine might have been a cardiovascular renal case. At all events, the patient had the condition, and the swelling was large enough so that it was circumscribed and scarified, relieving the symptoms, and the man recovered, though he had exhibited all the focal symptoms described. He may have another attack later. The question of epilepsy is very important as to the possibility of some local troubles being responsible for the epileptiform attacks, and those cases may safely be decompressed, and I think many of them would be improved if not relieved entirely. As Dr. Sterne suggests, I believe there is a swelling of the cells which surround a certain definite area in the pia-arachnoid and unquestionably in the localized territory of the cortex, but a swelling here can be relieved just as well by decompression and scarification as it can elsewhere. The astereognostic sense was limited and localized and defined very definitely. It was carefully worked out and found to have absolutely disappeared within two weeks after operation. I think that proves we struck the right point, because an exudative and perhaps inflammatory process was found, though typically edematous in appearance.

ETIOLOGY OF THROMBO-ANGIITIS OBLITERANS (BUERGER) *

WILLY MEYER, M.D.
NEW YORK

On the basis of extensive clinical observation and a variety of laboratory examinations of patients suffering from the so-called thrombo-angiitis obliterans (Buerger), some points that may prove of interest are presented herein as tentative conclusions. They may have to be revised from time to time as our knowledge of the disease deepens.

Chemical analysis of the blood of these patients has shown that:

1. There is no retention of waste nitrogenous constituents.
2. There is no marked decrease in the alkaline reserve of the blood, as demonstrated by the carbon dioxid combining power of the blood plasma (method of Van Slyke).
3. In all the cases thus far studied, the ingestion of 100 gm. of glucose, after a brief fasting period, has produced hyperglycemia.

This observation shifts the whole question of the etiology of the disease to new ground, and the old designations appear no longer appropriate.

For the present I would propose naming the disease "glycophilia," and shall so call it in the course of this paper. The similarity of the name to "hemophilia" is intended to point to sex limitation and other obscure features of the disease.

GENERAL CHARACTERISTICS OF THE DISEASE

The disease usually develops soon after puberty, rarely after the fiftieth year.

Abuse of tobacco, particularly excessive smoking of cigarets, may occasionally be a contributory etiologic factor, though some patients afflicted with this disease

---

* Read before the Section on Surgery, General and Abdominal, at the Sixty-Ninth Annual Session of the American Medical Association, Chicago, June, 1918.

have claimed they are very moderate cigaret smokers. The disease is a chronic one, usually extending over many years. Periods of activity may alternate with periods of quiescence.

* Blood cultures negative.

The early symptoms are: pains in the calf of the leg on walking (intermittent claudication); spontaneous, uncontrollable pains in the toes, feet and legs, especially during the night, when in horizontal posture. Later on, the arteries usually become occluded and spontaneous gangrene develops. The upper extremities also may become affected.

GENERAL CHARACTERISTICS OF THE PATIENTS

All the patients we have had have been males; women seem to be immune.[1] They were all Jews of the poor classes who had emigrated from Russia, Poland, Galicia or Roumania—countries whose population is known to be especially subject to disturbances of sugar metabolism. This particular type of poor immigrant Jew has for ages been living under most insanitary conditions, closely confined and forced into intermarriage. They are hereditarily heavily encumbered; amaurotic family idiocy is specific among them; diabetes is a frequent disease; at one clinic it was associated with tuberculosis in 60 per cent. of the cases, against from 6 to 27 per cent. in other countries than those named above, according to general diabetes statistics. In one of my recent cases Irish descent was claimed. Investigation disclosed an Irish mother and a Polish Hebrew father; the son (my patient) had been left in ignorance of his father's descent.

Patients afflicted with a similar trouble are said to have been found also among the Swedes in Wisconsin and Minnesota (Ochsner), among the Japanese (Koga), in Cuba and in Persia, but the identity of the disease found in these countries with that of these Jews has not been proved.

The majority of the patients have a high red blood count and proportionately high count of blood platelets.

In trying to find a donor for blood transfusion in these individuals, three years ago, it was seen by the serologist of our hospital, Dr. A. L. Garbat,[2] that they all belong to a special class.

Almost all the patients seen by us have flatfoot.

INVESTIGATION OF THE DISEASE

On previous occasions I have given expression to my conviction that the disease under discussion would turn out to be a blood disease. I determined to get more light on this question, if possible. Therefore, beginning with February of this year, during my service at the Lenox Hill Hospital (formerly the German Hospital) of New York, I arranged for the admission of a limited number of these patients and had their blood examined in every conceivable direction by Dr. Adolf Bernhard, the pathologic chemist of the hospital, to whom I am greatly indebted for his untiring cooperation (Table 1). After a series of negative results in various directions, we found a disturbance of the sugar metabolism.

The sugar tolerance in glycophilia has been studied in fifteen patients up to the present time. The results thus far obtained are embodied in Table 2.

The concentration of sugar in the blood of fasting normal individuals varies from 0.08 to 0.10 per cent. When 100 gm. of glucose are ingested, the sugar concentration of the normal individual does not rise above 0.15 per cent. at the end of one hour, and by the end of the second hour the concentration of blood sugar has again returned to the normal or to a somewhat lower level. If the concentration of blood sugar one hour after the ingestion of the glucose reaches a higher level than 0.15 per cent., hyperglycemia exists.

This hyperglycemia may be accompanied by glycosuria. In the cases studied, the fasting level of the blood sugar varied between 0.096 and 0.168 per cent.

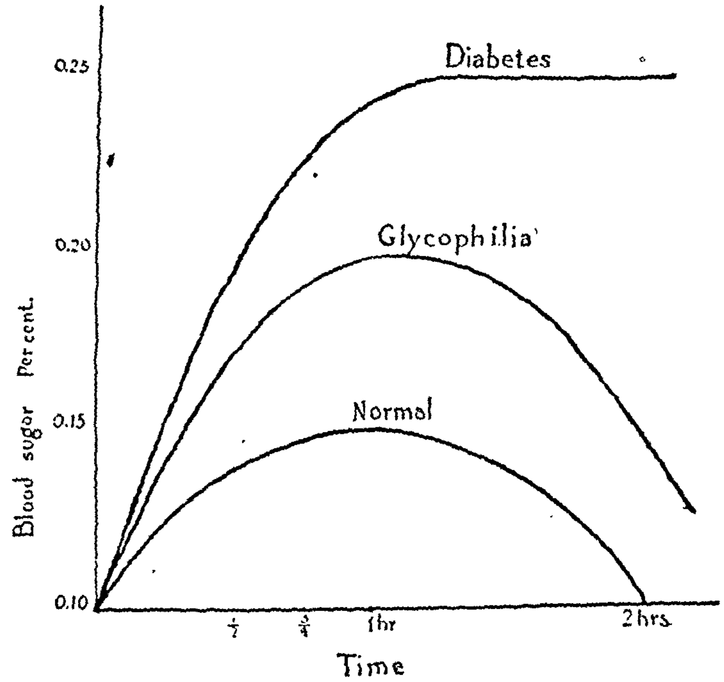
[1] In a recent case hyperglycemia was also found in a Jewess who complained of continuous cold sensations in her feet and showed absence of pulse in both peroneal arteries.

[2] Meyer, Willy: Conservative Treatment of Gangrene of the Extremities, Ann. Surg., 1916, 63, 280.

In seven cases the concentration of blood sugar before the ingestion of glucose was higher than the normal figure, varying between 0.116 and 0.168 per cent. In other words, some of these patients come to us with a certain degree of hyperglycemia, without having taken the glucose.

One hour after the ingestion of 100 gm. of glucose, the blood sugar concentration in these patients varied between 0.138 and 0.248 per cent., whereas in the normal individual, as already stated, it does not rise above 0.15 per cent. Two hours after the ingestion of the glucose, the blood sugar concentration varied between 0.10 and 0.215 per cent.

One case, M., No. 2498, did not show a *marked* increase in blood sugar concentration after the ingestion of glucose, it being 0.138 per cent. one hour later. However, this case showed the highest concentration of blood sugar after two hours, at which time it was 0.215 per cent. It is the only case in our series that shows a higher concentration of blood sugar at the end of the second hour than at the end of the first hour.



Comparative blood sugar curves after ingestion of 100 gm. of glucose.

In six other cases the blood sugar at the end of the two hours did not reach the original level obtained before the ingestion of glucose.

The results of these investigations indicate some disturbance in the carbohydrate metabolism of the patients. The studies are being continued in our hospital, and their progress will be reported from time to time.

The general clinical aspect of these cases in many respects shows such a close similarity to what we are accustomed to see in cases of diabetes mellitus that their classification as "near diabetics" appears justifiable, and I fully expect to find this diagnosis verified after the study of a greater number of cases.

The characteristic difference in the sugar tolerance of healthy individuals, glycophiliacs and diabetics is diagrammatically shown in the curves in the accompanying chart.

The probable cause of hyperglycemia in glycophilia, and also of the erythrocytosis which is frequently found combined with it, I expect to take up soon in another communication.

The chemical blood analyses of Dr. Bernhard appear to justify the above proposed change in the nomenclature of this trouble. "Thrombo-angiitis obliterans"—the name given it by Dr. Leo Buerger of New York—implies a thrombus formation, due to inflammation of the blood vessels. I do not believe, however, that the occluding masses within the small arterial blood vessels are really thrombi, nor do I believe that an inflammatory process of the blood vessel walls plays a rôle from an etiologic point of view.

I am rather inclined to explain these masses as originally being a conglomeration of red blood corpuscles due to erythrocytosis and stasis, the latter being a sequence to the increased viscosity of the blood. They may appear to the eye of the pathologist, macroscopically and microscopically, as thrombi. Yet, I feel that microscopic lenses of higher power than we know at present will probably show them to be something different.

This is also the reason why the name "thrombophilia," which I recently proposed[3] for this disease, has been discarded.

CLINICAL OBSERVATION AND TREATMENT

In my service at the Lenox Hill Hospital five beds were set aside in the early part of this year for the study and treatment of glycophilia. They have been constantly occupied by these patients, and for weeks at a time by the same men. At certain periods it was necessary to increase the number of beds to seven. I feel the need of at least fifty beds for this purpose. But to have set aside more than from five to seven would have crippled the service.

In order to handle with these limited facilities the greatest possible number of individuals, I have endeavored to shorten the time required for their treatment at the hospital. Out of the first empiric steps and the feeling of our way, a sort of routine has gradually developed, as follows:

On the patient's admission to the hospital a complete chemical analysis of his blood is made, also a complete blood count, platelet count and Wassermann test. Then the sugar tolerance test is carried out. According to our present view, a positive result places the patient in the glycophiliac class, and he is retained for treatment.

In order still further to cut down the time required for preliminary examinations and to save several days of hospital attendance, the blood tests and the sugar tolerance tests have of late been made in an ambulatory fashion at the dispensary. The work there has been placed in charge of a special assistant, Dr. M. Greenberger.

A most conspicuous feature in the picture of glycophilia seems to be a considerable dehydration of the tissues. A glycophiliac may be compared to a flower withering for the want of water. Our treatment, therefore, consists in supplying an abundance of water to the system.

From the start, the treatment is intensive. It aims at producing quickly the highest possible degree of hydremia. This is obtained by the simultaneous use of duodenal flushing with the help of Einhorn's duodenal tube, as suggested by McArthur[4] of Chicago, combined with hypodermoclysis. In duodenal flushing, from 8 to 10 quarts of Ringer's solution, or a solution of sodium bicarbonate (from 15 to 30 gm. of the salt per day) of body temperature, are given by the rapid drop method within twenty-four hours. Ringer's solution or a solution of sodium bicarbonate seems to have a better effect than plain water.[5] In duodenal flushing the actual absorption of the water into the system by way of the blood has been proved by the fact that about as much urine is discharged as water is poured into the intestinal tract.

---

[3] Report of Surgical Section, New York Academy of Medicine, Med. Rec., New York, 1917, **92**, 262.

[4] McArthur, L. L.: Surg. Clinics, Chicago, 1917, **1**, 499.

More recently we have made the patient buy the tube before he enters the hospital. Here he is taught its use, and as soon as he has learned it, he is sent home to continue the treatment there for from three to five weeks, provided it is a mild case; if he represents a more serious case, he remains at the hospital for additional hypodermoclyses. We are now about to transfer to the dispensary the giving of hypodermoclyses, and we are arranging for three treatments per week for each patient, under special supervision. Of course, only patients who are able to walk can be subjected to such ambulatory treatment.

Hypodermoclyses are given with the maximal quantity of Ringer's solution the patient can endure, and repeated daily, if possible. Intravenous infusion of Ringer's solution is not resorted to, because the aim is the attainment of the greatest possible penetration of fluid into the body tissues. Extensive literature shows the latter to remain quite dry when the liquid is introduced intravenously.

The injection of such quantities of fluid is made principally for the purpose of reducing the viscosity of the blood and thus enable it to pass again through the narrowed arterial channels.

During this treatment the condition of the patient occasionally runs the following course: The incessant, most excruciating pains, not controllable by any other means, decrease in intensity. At first only a few hours of sleep can be enjoyed by the patient while sitting upright, for the night, in a chair. Soon he goes to bed and keeps the affected leg hanging out; then he risks lifting it to a horizontal posture; eventually he rests comfortably in bed, free from pain.

The foregoing refers to patients without local gangrene, either of the superficial or deeper tissues. If gangrenous lesions of the skin and subcutaneous tissues are present, it has been found best, as regards saving time in the treatment, and particularly in alleviating the pain, to touch the ulcerative spot *lightly* with the actual cautery. The sealing of the hypersensitive sore does away with a good deal of pain. Under the scab, often healthy granulations form which tend to more rapid healing. Sometimes the eschar stays on until cicatrization of the formerly obstinate wound is completed. The light, dry gauze dressing is changed as little as possible during the time that the artificial hydremia is being maintained.

In the majority of cases the deeper tissues, particularly periosteum and bone, are affected. Often it will be seen that what at first glance appeared to be a paronychia is a necrotic osteoperiostitis of, say, the third phalanx of the toes or fingers. This may have the tendency to invade the central cavity of the bone, and later involve the interphalangeal joint; or it may be that a seemingly superficial gangrene, for instance, over the os calcis laterally or at the calx itself, runs straight down to the bone. If conservative treatment is at all contemplated in a case like this, it is unwise to treat these wounds with all kinds of dressing, until the demarcation line has formed. Circumcision of the necrotic tissue with a knife, and the use of the actual cautery on the surface of the fresh wound, are better. Although with the latter procedure it will take a long time before the wound heals, the patient's pains are often much lessened.

When it comes to operating—enucleation or amputation—I prefer to undertake the operation after the patient's system has been thoroughly permeated with fluid. It may then be sufficient to enucleate or amputate a toe or a finger, where formerly larger parts of the extremity had to be sacrificed. In other cases, amputation below the knee will give a good result, while without the preceding hydration of the system, amputation above this joint would probably have been required. It almost seems as if this temporary saturation of the system with fluid would enable us to operate more peripherally, with greater and more frequent success, than could be obtained formerly. Further experience is needed definitely to determine this point. Probably the degree of improvement in the circulation and the condition of the blood will differ in different individuals.

Without doubt there are abortive cases of the disease. A most remarkable consequence of the treatment in some cases has been the restoration of pulsation in arteries over which, before the treatment, no pulse could be felt. Koga observed the return of almost normal pulse in ten out of thirteen Japanese cases, after a course of hypodermoclysis. I have seen it in only a few instances. Still, I have seen it, and the mere fact that pulsation does return in previously pulseless major arteries—or, expressed in other words, that occluded arteries become again patent, and within a comparatively short time—makes me look with doubt on the theory that ascribes the occlusion to thrombosis. It rather inclines me to attribute the occlusion to stasis, as far as the arteries are concerned. In the veins the occlusion is probably a true, though secondary, thrombosis.

Patients without gangrene are discharged as soon as their pains have subsided. When this goal is not reached, ligation of the deep femoral vein below Poupart's ligament, or amputation, is performed. In spite of one very good result of arteriovenous anastomosis between the femoral vessels in Scarpa's triangle, in one of my patients, aged 31, I could not make up my mind thus far to have this operation take the place of a regular intermediate step, before amputation is resorted to.

However, be it specially emphasized, none of these patients are cured; they are merely improved, whether or not operation is done. In either event, their trouble returns sooner or later. This, at least, has been the rule so far. Of course, there may be fortunate exceptions. The reason for this fact is that the underlying cause of the disease is as yet unknown, and until it is known, we cannot hope to bring more than temporary relief to these patients. Our treatment, conservative as well as radical, thus far has been only palliative. True, after amputation of the leg, the old tormenting pains subside as by magic; but the disease goes on nevertheless. Frequently the other extremity after a while shares the fate of the one amputated, and still later on, the upper extremities may be attacked. Proof of the continuance of the disease after the discharge of the patients, with their symptoms improved and their wounds healed, is the fact that they are usually unable to do much walking without getting pains and becoming excessively tired.

---

[5] In making up Ringer's solution we have employed the tabloids furnished by the firm of Burroughs Wellcome & Co., dissolving two tabloids in 1 pint of water. Each tabloid contains: calcium chlorid, 0.05 gm.; potassium chlorid, 0.05 gm.; sodium chlorid, 2.25 gm.; sodium bicarbonate, 0.025 gm., and glucose, 0.25 gm. One tabloid dissolved in 250 c.c. of water forms Ringer's solution.

We put these discharged patients on a mild antidiabetic diet and advise them to take up work that will not unduly tax the muscles of the respective extremity, although the latter advice is usually difficult to follow for this class of mostly poor patients. They are further instructed to report back for blood examination at varying intervals, according to conditions present.

Much work remains to be done to clear up this fascinating affliction. I am convinced that it is primarily a disease of the blood of endocrine origin—due principally, perhaps, to a disturbance in the normal function of the suprarenals—and not a disease of the blood vessels. Should we succeed in tracing it back to its original cause and then find a way of correcting the disturbance, not only untold suffering would be spared these pitiful patients and their families, but vast sums of money saved to the country at large.

CONCLUSION

Although the number of cases studied is small, the results thus far obtained definitely show that there is something defective in the carbohydrate metabolism of these patients.

Regarding the theory I have advanced above, that one or more glands of internal secretion are pathologically affected and cause the disturbance, I fully realize that it rests as yet on slender support. But I take kindly to this theory, because it tends to remove the disease from the realm of the mysteriously obscure, and brings it into the purview of an already thoroughly explored field of medicine, thus making available for its elucidation a vast treasure of experimentation already laid down in literature. However, even with this help, the task of finding a path through the many contradictory observations and apparent inconsistencies is altogether too big for individual effort, and recognizing this to the full, it seemed to me best to make known at this time what we have found thus far and to urge the cooperation of all those who are called on to treat this class of patients.

The best way to make real progress in this matter would be to get some philanthropist interested in the subject and induce him to equip liberally and endow a commission, composed of specialists from the various fields of medicine involved and having for its sole object the study of glycophilia.

700 Madison Avenue.

ABSTRACT OF DISCUSSION

Dr. V. L. Shrager, Chicago: It is very sad that this condition is not better understood, particularly clinically. It does not matter so much that we do not know what the cause is at this time. At Mount Clemens, where I have been a patient myself, many patients were treated for rheumatism when they had only the early stages of thrombo-angiitis obliterans. Flatfoot is frequently associated with angiitis obliterans, which suggests an anatomic theory. Oppenheim and a few others have found that these patients have a congenital smallness of the blood vessels. Many of them, whether treated or not, develop epigastric distress and excruciating pain. I have seen cases of spasm of the epigastric region entirely ignored. The angiospasm is very much the same as a cramp in the calf of the leg. I must say in defense of the Ringer solution that while it does not modify the disease, it is a blessing to the patient. I have never known any of them that did not get absolute relief. I have extended the use of Ringer's solution to trophic diseases of the foot and other diseases. I have treated several cases of diabetic arterial changes, and I have found that Ringer's solution gives them a great deal of relief.

Dr. Willy Meyer, New York: Dr. Buerger has made careful pathologic studies of the type of the blood vessel occlusion. I so far would disagree with him with reference to the interpretation of his findings. Our laboratory examination has shown the hyperglycemia often before the ingestion of glucose, surely soon after. I believe that these patients are "near-diabetics." Such assumption will explain easier also the cases with open blood vessels and gangrene, as in diabetes. From the standpoint of symptomatic treatment we can best improve the condition of these patients by pouring as much fluid into their system as possible, particularly by using the duodenal tube. Nobody can drink 8 to 10 quarts of fluid a day for a number of weeks. That the fluid is actually absorbed and not to greatest extent discharged by the rectum is shown by the large amount of urine voided by these patients. As a matter of course, some fluid is retained in the system.

Regarding surgical treatment, it seems unwise in patients with superficial gangrene to wait for further developments. We should act immediately and touch the gangrenous spot lightly with the cautery; under the eschar the wounds often heal. If we remove the nail in a patient with what appears to be a paronychia, we will often find under the same an osteoperiostitis, not infrequently combined with osteomyelitis, of the third phalanx, which seems to be a reactive inflammation to localized bone gangrene, and if treated properly will greatly relieve the pain. A most interesting observation, which will be valuable if corroborated by further clinical data, is, that if we pour a large amount of liquid into the system of these patients, a required amputation can likely be done more peripherally; in other words, we may with it, for instance, more often be enabled to amputate below the knee rather than above the knee without recurrence of gangrene. If we should be able to find the cause of this disease and correct it, certainly great expense would be saved to the community at large, not to mention the unspeakable suffering of these patients and their families. For the trouble is comparatively frequent, especially in the large centers of our country, and those stricken by the disease always spend months and years in hospitals.

Mortality Among Women from Causes Incidental to Child-Bearing.—Between the ages of 15 and 44 the diseases and conditions incidental to child-bearing account for more deaths of women than does any other disease or class of diseases except tuberculosis. This statement is made by Louis I. Dublin, of the Metropolitan Life Insurance Company, in an article on a study of mortality among women from causes incidental to child-bearing, and it is based on the records of death of a large number of insured women in the industrial department of the Metropolitan company. During the six year period, 1911 to 1916, covered by the study, it is estimated that 14,694,260 insured women between the ages named were under observation. From this number 10,056 deaths occurred from diseases and conditions incident to childbirth, in the ages between 15 and 44. Most important of these diseases was septicemia, which was responsible for 4,321, or 43 per cent., of the total. Albuminuria and convulsions caused 2,654, or 26.4 per cent., of the total. It will be seen that these two conditions accounted for 69.4 per cent. of the total deaths from causes incident to childbirth. The figures relating to mortality on account of childbirth in the Metropolitan company are steadily improving, due, as is said, to the extension and improvement of the prenatal and postnatal nursing service inaugurated in 1909. In 1916, of a total of 160,843 women policy holders visited during illness, 41,572, or 25.8 per cent., were cases resulting from diseases or conditions incidental to the puerperal state. In the period between 1911 and 1916 the death rate among white policy holders from these causes fell 10.7 per cent., the decline in mortality from septicemia being 17.3 per cent.

RELATIONSHIP OF FOCAL INFECTIONS TO CERTAIN DERMATOSES

FURTHER OBSERVATIONS *

M. L. RAVITCH, M.D.
AND
S. A. STEINBERG, M.D.
LOUISVILLE, KY.

The present paper is in a way a continuation of a former paper,[1] and a review of the conclusions presented then in the light of further observations and experience. We were very much pleased when we were asked to choose this subject, for it is a field in which we feel ourselves comparative pioneers. As far back as 1905, we reported[2] cases which we considered due to hematogenous infection of the skin. Of course, we lay no claim to priority in this field; it is very well known that, according to Gosse,[3] Mackenzie called attention to the connection between rheumatism and erythema nodosum in 1886, and since that time numerous references have been made to a connection between rheumatic infections and various dermatoses. However, it was not until the epochal work of Billings and Rosenow that we really had a base of facts from which to work. With the proved relationship of focal infections to more or less widely disseminated infection throughout the body we found ourselves in a better position to prove that the skin may suffer from such infections as well as the joints, muscle, heart, nerves, and other structures.

Now if we dermatologists have one fault, it is that in our enthusiasm, in our desire to clear up the many problems of diagnosis and etiology, in our efforts to place our treatment on a really scientific and rational basis, we have more than once gone to the extreme in taking up new fads and theories. How often what we have acclaimed one day we have had to renounce the next! Theories have come and gone — uric acid diathesis, autointoxication, trophoneuroses, internal secretions, anaphylaxis, focal infections—each hailed by the enthusiasts as the explanation of all the unsolved problems. Only too often the pendulum swings as far to the other extreme when the reaction comes, leading to denial of any value to the theory or to neglect of study of the subject entirely. Now this is ever our danger: that we are apt to lose our impartial judgment and render valueless any observations we have made, owing to prejudices and preconceived theories; we take sides in a controversy before we have sufficient data at hand. Rather should we make it a point to take no sides in controversial argument, but to act as impartial judges in bringing out all the evidence, then, as impartial jury, weigh its importance. We should be careful not to minimize, distort or conceal any evidence which may be opposed to what we have already begun to believe, nor to exaggerate what tends to prove our views correct. In this way we shall the sooner arrive at well founded conclusions on which further investigations may be based; in this way we shall more surely get all the possible value out of any subject, and in this way we shall avoid the errors of faddism in which all of us have fallen at some time. It must be remembered, too, that even if we are disappointed by finding that what promised to open up a tremendous field in diagnosis or treatment has proved to be quite otherwise, still we have not wasted our time entirely; we shall have gained knowledge at least, and with every investigation we narrow down the number of possible causes and make more certain the ultimate solution of our most dfficult problems.

RELATION OF DERMATOSES TO FOCAL INFECTIONS

For several years now we have been trying to determine what connection there might be between any of the dermatoses and the focal infections or infections commonly considered as usually or frequently due to focal infection. We tried not to allow ourselves to be influenced by any preconceived ideas; even when the dermatosis was of a character that made it certain to us that such infection could play no part, still we have made it a point to inquire about previous attacks of sore throat, tonsillitis, pyorrhea, abscesses in the mouth, antrum and sinus infections, pain around the joints or in muscle, nerve or tendon, endocarditis, pericarditis, varicose ulcers, appendicitis and similar infections. Also we have examined the mouth, throat and nose in practically all cases. In many cases we were unable definitely to locate any focus of infection, although we were fairly sure of its presence, owing to the expense and time which would have been necessary for a thorough examination.

In many other cases we were unable to disprove the possibility of a focal infection, even though we felt that there was no evidence of such infection, owing again to the impossibility of making the necessary examinations in every case. Patients with a slight dermatosis are not willing, as a rule, to have their teeth examined by the roentgen ray, suspicious fillings removed, their throats, antrums and sinuses examined—it simply is not feasible in the great majority of cases. What we can do and what we have tried to do is to get a thorough history of the presence or absence of any signs of focal infection, of any rheumatic attacks or allied conditions, and then note the state of the tonsils, throat, nose, mouth and teeth. This does not exclude, we admit, the possibility that the patient has an unsuspected infection in one of the sinuses, a pyosalpinx, a cholecystitis, vesiculitis, cystitis, prostatitis, appendicitis, any of which conditions may be present without pain or other appreciable symptom, even without apparent effect on the patient's health; also any of these conditions might furnish a constant or intermittent stream of infection or products of infection, whereby direct or indirect reactions in the skin might be caused without other tissues or organs being affected sufficiently to cause symptoms.

The burden of proof, however, certainly lies with the affirmative and we should not be asked to believe that a person without discoverable focus must have a focus because he has a dermatosis which we are trying to connect with such infections. It is bad enough to be offered the mere presence of a focus of infection as proof of the same connection. In the first place, the mere coincidence of any dermatosis with foci of infection should be considered as suggestive only. We must remember the many possible conditions which may act as foci of infection; we must remember how many people have one or more of these conditions, and how few people are actually free from any focus whatever. Since many people suffer from

---

different foci of infection without any skin manifestations, it is not surprising that we find many dermatoses coincident with focal infections; the wonder is that we find so many in whom no focus can be found. At any rate, the proportion of persons having some focus of infection is so large, that to find a high ratio in some dermatosis is not enough. The ratio must be distinctly higher than the usual ratio. The coincidence of focal infection and a dermatosis is by itself practically proof of nothing. It merely serves to add value to other evidence.

FURTHER OBSERVATIONS

There are other ways in which we may endeavor to determine the connection than by noting coincidence of the two. For instance, when the recognized treatment has been given a thorough trial and failed and there are undoubted foci of infection, the dermatologist is warranted in doing what he can to persuade the patient to get rid of these foci, not only for the possible effect on the dermatosis, but because we know that these foci are constant menaces to the patient's health. We then have the opportunity to study the effect on the dermatosis after the removal of the focus. The tendency of many dermatoses to disappear spontaneously must be remembered, and therefore we must not accept too readily the often temporary improvement that follows tonsillectomy or other procedures as proof that the focus removed was the etiologic factor in the case. Before these cases are recorded as evidence of anything they should be watched over a long period, and relapses or recurrences noted, also any other symptoms of focal infection, for all foci may not have been removed, or a little tonsillar tissue left in the tonsillar bed may become hypertrophied and cause more trouble than before. There are, of course, many other methods of gathering proof in these cases, such as pathologic and bacteriologic examination of the lesions to ascertain whether direct infection of the skin has occurred and whether this infection is of the same character as in the focus. As our various methods of differentiating strains improve, we may hope to be able to recognize subdivisions in the streptococci, staphylococci and other forms, just as we have succeeded already in dividing the pneumococci into four types according to their serum reactions, also the meningococci and parameningococci, and the typhoid and paratyphoid. Experimental inoculation with the different strains should prove of greater value, too, when we can distinguish between the strains. Experiments on the effect of injecting sterilized pus from closed foci may prove enlightening by showing the possible action of such pus in causing anaphylactic or toxic reactions. However, we, as dermatologists, are more concerned now with what has been discovered and what we may discover through clinical observation.

INFLUENCE OF FOCAL INFECTION IN CERTAIN DERMATOSES

Fairly early in our work we noticed that we were more suspicious of a focal infection cause for erythemas than for any other dermatosis. This was partly due to our knowledge of the work of Rosenow and others in erythema nodosum, partly to the fact that we encountered many forms of erythema in mild and severe septicemias, rheumatism and similar conditions. Several cases of erythema multiforme, exhibiting many small hemorrhagic lesions and occurring during early stages of generalized joint, heart and kidney infection came under our notice. Study of these lesions revealed that they were practically small abscesses, infection of the capillaries with cocci, with damage to the endothelium and adjacent tissue, hemorrhage and infiltration with round cells, sometimes small necrotic areas; however, the necrotic areas were too small, the extension of the infected area too limited, the proteolytic action too feeble to often result in the macroscopic formation of pus or extension of the pus to the surface. The lesions usually retrogressed during favorable progress of the case and fresh crops appeared during relapses. The extent of the dermatosis was not a measure of the severity of the case, since the dermatosis was entirely absent in several severe cases and present in mild ones. Erythema iris was encountered in several cases of acute exacerbation of chronic rheumatism. Cases of erythema nodosum usually occurred in rheumatics, though not necessarily during exacerbations or acute stages. On the other hand, we have had typical herpes iris, as well as other forms of erythema, in which we could demonstrate no focal infection and which had no other symptoms of any kind. Although some of the cases of erythema which we considered of infectious origin showed certain characteristics not usually seen in noninfectious erythemas, there was absolutely no difference in the appearance of the erythema iris cases as far as we could judge, whether they were of infectious origin or otherwise.

The urticarias and angioneurotic edemas were probably next to the erythemas in apparently showing connection with rheumatic or focal infection; yet here, too, the majority of such cases did not seem to us at all so connected. These cases, especially the urticarias, nearly always show an eosinophilia, and experimental work in anaphylaxis has shown such an intimate connection between the anaphylactic reaction and eosinophilia that this alone would turn our attention to the possibility of anaphylaxis playing a part in the causation of these dermatoses. Combine with this the appearance of urticarial eruptions as one of the symptoms of experimental anaphylaxis and the well known fact that urticaria often appears following ingestion of certain foods or exposure to certain animals or plants in susceptible individuals, and we have a fairly firm connection established. If the focal infections, then, are the cause of certain urticarias it is natural to suspect that it is through an anaphylactic phenomenon, although it is possible, of course, that this may not be true in any or all these cases. With the angioneurotic edemas one would include the possibility of there being an actual infection or toxic irritation of certain trophic nerves.

We might divide purpuras into three classes: (1) cases accompanying focal infection, especially rheumatism, and probably due to that cause; (2) cases due to anaphylaxis, and (3) cases of unknown or other origin.

Herpes zoster has been attributed to infection of the posterior root ganglions. Cocci have been found present in this tissue and a similar infection has been produced by injecting this coccus into the blood stream. We can only say that we have seen very few cases of herpes zoster that were due to infection, but we have seen many cases certainly due to other causes, such as arsenic. In some cases we could find no focal infection nor other explanation. In some cases the patient gave a history of trauma or exposure; these may have been due to focal infection lodging in chilled or injured nerve structures. Evidently a herpetic eruption may result from irritation of certain nerve structures and this irritation may occur in more ways than one.

Among the eczemas we find cases of such widely varying etiology that it is possible that focal infection may be among the causes. We have seen eczemas due to nephritis and disappearing when the renal function was restored sufficiently. We have seen eczemas which are considered due to disturbance of internal glandular sécretion, such as the breast-fed babies of hyperthyroidic mothers, and the eczema cleared up promptly when the baby was taken from the breast and given a little iodid. We have seen eczema from surplus of carbohydrate or fat in the diet; at least, correcting the diet resulted in a cure. We have seen trade eczemas; when the patient stopped working in the chemical, drug or other substance responsible the eczema yielded to mild external applications. And we have seen many cases of eczema in which we could find no cause, search as we might. We have not in our own practice seen any case of eczema which we thought due to focal infection. We admit the possibility of a toxic action on the skin from such a focus producing an eczema and we have reported a case apparently due to an ulcerated appendix.

Scleroderma has usually in our experience been easily connected with disturbance of thyroid secretion. If focal infection plays any part in its causation we should judge that it must be through affecting the thyroid. No other mode of action seems feasible to us.

Vitiligo we mention only because it has been mentioned in this connection. We absolutely fail to see how the two can be connected.

Psoriasis, also, must be considered. In the first place, various authors have written of a rheumatic factor in this disease; Chipman[4] reports finding apical abscesses in several psoriatics. Autogenous vaccines from the patient's throat or tonsils have been employed; in fact, we have tried out some experiments along this line in our own laboratory during an investigation into the cause of psoriasis. Our conclusions then are our beliefs now: that psoriasis is not due to an infection of the skin structures; it is not due to a communicable virus in the skin or blood; it cannot be transmitted by any way that we know; it occurs in individuals who may be otherwise perfectly healthy; the attacks do not occur with any relationship to rheumatic attacks; lesions in rheumatic patients show no sign of clearing up with amelioration of the rheumatic symptoms; the lesions likewise show no relationship to tonsillitis or sore throat, so that, thus far no connection has been established between focal infection and psoriasis, and we do not think there is any.

Lichen planus seems as unlikely to be due to focal infection as any condition we can mention. We grant, not for the sake of argument, but to avoid argument, that it might be possible for the skin to react in all these totally different and diverse ways to various focal infections, forming an erythema in one person, a psoriasis in another, a vitiligo in another, a wart in another, a freckle in another, but we do insist that it is too far fetched to insist for a moment that the skin really does react to these mysterious and diversified influences in such limited types of infection as we are now considering.

OTHER FORMS OF INFECTIONS

There is another group of cases of which I wish to speak—cases due to internal blood-borne or lymph-borne infections, yet not true focal infections by any means. For instance, furunculosis and carbunculosis may be local infections at first, then gain entrance to the blood stream and appear in other parts of the body for months and months. Erysipelas following infected wounds, or even septicemia, belongs to this group, too. Somewhat different from the foregoing are those erythematous lesions of nose, throat, or face commonly associated with ulceration in the nose, fistulas of the gums or other infection in adjacent tissue. One or two cases of acne rosacea have seemed to come in this category, although the majority show no connection with focal or other infections unless local and external. The other types of acne were never associated wth focal infections in our experience.

SUMMARY AND CONCLUSIONS

To sum up what we have gathered from our own observations, the observations of other dermatologists, correlated material from internal medicine and other specialties and the reports of the pathologists and bacteriologists, we present the following conclusions:

1. If we are to gain information from observation we must try to maintain a strict impartiality.
2. We must use other methods of gaining knowledge in this field, such as laboratory experimentation.
3. We must remember the large percentage of people who have one or more form of focal infection and not accept a certain number of coincidental cases as proof.
4. Though we acknowledge other ways than direct infection of the skin by which focal infections may be causative of dermatoses, still we must not assume, without direct proof, a hypothetic power of focal infections to cause such a variety of reactions as has been mentioned in this connection.
5. Focal infections—and in that class we include those conditions, such as arthritis, endocarditis, neuritis and similar affections, which, it is now admitted by most authorities, may result from such infections—are causative of a small percentage of such dermatoses as the erythemas, urticarias, purpuras and perhaps herpes zoster.
6. Some cases of the dermatoses just mentioned which have lesions identical with the conditions referred to, are not due directly or indirectly to focal infections.
7. We can see no relationship between focal infection and such dermatoses as psoriasis, lichen planus, pernio, acne, vitiligo, scleroderma and alopecia areata.
8. Although these conclusions are based on work covering several years and a careful study of the work of others, still they are only tentative, not final; we expect them to be changed, more or less; we are not taking either side in this matter, but are open to correction from the experiences and experiments of others, recognizing that our entire point of view may be changed tomorrow.

Sudden Paralysis of Ocular Muscles.—Wertheim Salomonson writes to the *Nederlandsch Tijdschrift* to call attention to seven cases recently encountered in which children and adults developed a sudden, peculiar paralysis of the ocular muscles. It was accompanied by gastro-intestinal disturbances only in a few, but he lists the cases as "botulism." The outcome was favorable in all.

THE ETIOLOGY OF LICHEN PLANUS *

ERNEST DWIGHT CHIPMAN, M.D.
(San Francisco)
Captain, M. R. C., U. S. Army
CAMP CRANE, ALLENTOWN, PA.

In discussing the etiology of lichen planus most writers have been content to enumerate certain generalities as to age, sex and environment, and to epitomize our ignorance in some such phrase as "the exact etiology is unknown" or "the causes are obscure." Of those who take a definite stand on the question, some hold the view that the disease is connected with infectious microbic agents or that it is due to a toxemia, while others believe it simply the outward expression of deranged nerves, a condition resulting from overwork, grief, worry or emotional crises.

VIEWS HELD REGARDING THE ETIOLOGY

In Great Britain, Norman Walker believes the anatomic appearances suggest an infective inflammation and cites a severe case of lichen in a professional golfer, inferentially indicating that the disease is not due to "nerves" because occurring in one who typifies the phlegmatic temperament; Malcom Morris, on the contrary, places lichen frankly among the diseases due to nerve disorder.

French writers, including Brocq, Darier and others, incline strongly to the theory of nerve influence.

Of the American dermatologists, Fordyce, Montgomery and Alderson and Engman and Mook suggest toxemic or microbic elements as the paramount etiologic factors.

One may roughly classify the opinions of these three schools of dermatology as follows: (1) British, divided; (2) French, favoring nerve theory; (3) American, tending strongly to theory of infection.

INFECTION FROM DISEASED TEETH

In connection with the pathology of the disease, Ormsby states: "Many observers believe that lichen planus is a constitutional disease with cutaneous manifestations, produced by an unknown toxic agent acting on the nerve centers." This approximates the view which it is the purpose of this paper to suggest, namely, that lichen planus may result from systemic toxemia or bacteremia, the origin of which is most often, if not always, in the teeth.

The theory of focal infection as the chief etiologic factor in lichen planus is not new even though it receives little if any notice in the most recent editions of American textbooks. It was definitely suggested before this section in one of the discussions at the 1915 meeting. It was mentioned again before this section in 1916, and was further the subject of extended discussion at the annual meeting of the American Dermatological Association in 1917.

If it may not seem too insistent the suggestion is respectfully reiterated before this section in 1918 that the most probable exciting cause of lichen planus is tooth infection. Further, so many reasons exist which suggest nerve involvement, we may tentatively add that the nervous system plays a complementary part in the production of the lesions to the extent that either special vulnerability to any toxic or bacterial substance obtains in certain individuals, or that definite tissue affinity is present for a special toxic or bacterial substance in any individual.

It would seem that ample clinical observation alone will suffice to establish the relationship of lichen planus with focal infection. If a part be conceded to the nervous system the decision as to whether it is a question of specific tissue affinity or simply one of diminished resistance following overwork, emotional excitement and similar influences must rest rather on the fulfilment of the usual laboratory postulates.

Unfortunately the exigencies of the military situation have prevented the elaboration of this idea as planned. It will be the aim of this paper, therefore, to present a short series of typical histories from private practice and to indicate a few reasons why tooth infections are frequently overlooked.

In addition to the case histories which follow, there might have been included, if available, the records of numerous others seen in hospital services in none of which was evidence of tooth infection lacking.

REPORT OF CASES

Case 1.—H. K., an ex-prisoner of war, who had escaped after passing through a period of marked mental stress, presented characteristic papules on the flexor surfaces of the arms and forearms as well as the trunk. Repeated and thorough treatments with arsenic and mercury both by mouth and subcutaneously, as well as local applications, failed to ameliorate the condition. Roentgenograms revealed apical abscess of a molar tooth. A few weeks after this he received proper surgical treatment, the lesions resolved and although a year now has passed there has been no recurrence.

Case 2.—Mrs. B., a stout woman, of nervous temperament, who was easily fatigued and easily irritated, presented marked papules on flexor surfaces of the legs and inner aspect of thighs, accompanied by severe paroxysms of itching. When referred to me the usual general and local remedies had been employed without avail. Roentgenograms revealed a definite abscess about a molar tooth which was removed. Following this treatment the patient went on a vacation to the country and in two months the cure was complete.

Case 3.—A. M., a middle aged man inclined to obesity, a heavy eater and smoker and a moderate drinker, presented a papular eruption on the outer aspect of both legs. Some of the lesions were discrete and some had coalesced into infiltrated patches the size of a 25-cent piece. The treatment consisted of restricted diet, avoidance of alcohol, tobacco and all stimulants, together with the internal administration of red mercuric iodid and the local application of the ultraviolet rays. Although the roentgenogram had revealed definitely abscessed areas about two teeth, the patient demurred when treatment of them was proposed. Under the treatment noted some improvement was registered, but a cure did not follow, and when later the treatment was relaxed an exacerbation occurred. On resumption of the treatment, improvement was again noted and the patient desired further delay before undergoing treatment for the abscesses of the teeth. When last observed the lesions, then of some six months' duration, were still apparent.

Case 4.—Mrs. H., a young woman with inclination to overweight and a somewhat nervous temperament, complained of widespread lichen planus papules involving the flexor surfaces of wrists and arms, the trunk, legs and thighs. When the possibility of tooth trouble was suggested it was promptly and vehemently repudiated on the ground that she had just paid a dentist $600 for professional services. Nevertheless, a series of roentgenograms was made and six infected areas were disclosed. The subsequent recommendations of a dental surgeon called for such radical treatment that the patient elected to suffer from lichen planus rather than undergo the surgical treatment indicated. The lesions, which were acute in type, responded in about ten weeks to treatment with red murcuric iodid internally and calamine lotion externally.

---

* Read before the Section on Dermatology at the Sixty-Ninth Annual Session of the American Medical Association, Chicago, June, 1918.

CASE 5.—Mr. A. was a middle aged man with classically arranged whitish papules on both lateral walls of the buccal cavity. This patient presented palpably diseased conditions of the teeth with pyorrhea. He came from a distance, was seen once only, and was advised as to treatment of teeth. Results not known.

CASE 6.—J. R., a man, aged 30, by occupation an electrician, presented typical lichen planus papules of both forearms. Examination of the teeth revealed an abscess of a crowned bicuspid tooth. Treatment of this condition was recommended, but the case could not be followed further.

CASE 7.—Mrs. A., an elderly woman, with no evidence of nervous temperament, complained of a papular eruption on the hands and wrists of one month's duration. Although several stumps of infected teeth were present, no treatment of them was attempted, because the lesions resolved under the internal administration of red mercuric iodid.

CASE 8.—Mrs. G., a middle aged woman of exceptional tranquillity and poise, came with characteristic papules of hands and forearms. Itching was severe. Rather prompt disappearance of lesions followed the use of biniodid of mercury. In one year there was a recurrence and the same treatment was not effective. On this occasion an abscessed tooth was found and treated. Recovery followed in a few weeks.

IMPORTANT FEATURES OF THESE CASES

Now an analysis of the general factors involved in these cases would possibly not vary greatly from that of a much larger series.

As to age, no patient was under 30; the average was about 45. The number of men and women was exactly the same. In only one patient was there history of marked emotional disturbance. Of the four women concerned, only two were to be classed as "nervous," while of the men not more than one would fall into that category, so that the proportion of those palpably nervous is possibly no greater among those suffering from lichen planus than in those free from it, at least as far as this series reveals.

The question of age is of additional interest because it is a common observation that lichen planus is rarely observed before the first two decades of life are passed. This squares perfectly with the assumption that it may originate in a tooth infection, for such infections occur with relative infrequency in those under 20 years of age.

SOURCES OF ERROR

In attempting to prove a connection between any condition whatever and tooth infection, certain definite principles must be established. Several years ago in one of the section discussions one of the members remarked that only a certain small percentage of some skin disease in his practice showed evidence of tooth infection. It has occurred to me many times since then that had he based his conclusions on data procured in the same way that I was procuring mine at that time, the results might reasonably be expected to have been even less convincing. When the conception of focal infection first became widespread it was my custom to inquire of the patient's dentist if there was a possibility of any infective area about the teeth. The percentage of positive reports was so small and negative reports were so often rendered, only to be nullified later by roentgenograms, the fixed rule became soon established that only work from approved laboratories was considered as having significance, and the opinion of no dentist was given any weight unless good evidence was at hand as to his qualifications to approach the subject from a truly surgical point of view.

The mere statement of a patient's dentist that there is no focal infection is insufficient; his statement may be correct, but in no case can the question of infection be conclusively settled without roentgenograms. Again, the fact that a patient claims to be toothless, except for the artificial variety, need not be convincing, for the reason that hidden stumps may be revealed under the searching eye of the roentgen ray.

Still another source of error is found in the failure to obtain cure after admittedly infected teeth have been extracted. I have had occasion to observe the unfortunate results which followed in several instances when such teeth were "pulled." By reason of the unsurgical procedure certain infective elements were left behind and these combined with the trauma caused the development of a secondary infective process of greater severity than the primary one.

In this connection it is gratifying to point out the work that is being done by Novitzky,[1] who takes the stand that any dead tooth left in the body will sooner or later become a source of local or systemic infection. Recently he has emphasized two points: (1) A microorganism, a poisonous protein, or a toxin introduced into the blood stream by way of cancellous bone would be more active than would be the same amount if introduced into the stomach, and (2) on account of ills resulting from the retention of dead teeth in the jaws and on account of the impossibility of rendering dead teeth permanently aseptic we must conclude that teeth should not be devitalized.

Novitzky's technic for the removal of dead teeth is partially described as follows:

> Under local anesthesia the gums and the periosteum may be cut loose and retracted along the entire side of the jaw if this is necessary in order to gain space for operating. If the gums are carefully sutured back in normal position against the teeth, reattachment will take place. Ordinarily it is sufficient to cut a triangular flap with the apex pointing to the gingival margin of the tooth to be removed. This flap is raised and held back. Enough bone is removed with the chisel to give access to the apical region. The tooth may be hooked out sidewise, either before or after the apical exploration and curettement, depending on whether or not the entire root length of the buccal plate has been removed. The external periosteum flap is pulled into the opening at completion of the operation with a suture.

The advantages of this technic are: The avoidance of fractures, the opportunity for complete currettement, the avoidance of septic bone, granulating and low grade suppuration.

This may appear as a digression from our subject. Its vital relation, however, will be felt by those who have had the unpleasant experience of seeing their patients grow worse instead of better on removal of dead or diseased teeth simply because the dentist to whom the work was entrusted did not base his procedure on sound surgical principles. Its importance in relation to the etiology of any disease lies in the fact that if we believe the infective focus removed clearly, when in reality it is more septic than ever, we are certain to entertain false opinions as to its relationship with the disease in question.

CONCLUSIONS

1. In the study of a limited number of cases the only constant factor was tooth infection.
2. The rôle played by the nervous system remains to be determined.

---

[1] Novitzky, Josef: Dead Teeth, New York Med. Jour., 1918, 107, 548.

3. Great care must be exercised in the diagnosis of infected teeth and the results of operation should not be used as the basis of statistics or opinions unless performed by a competent surgeon.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. RAVITCH AND STEINBERG, AND CHIPMAN

Dr. Richard L. Sutton, Kansas City: I have been impressed with Dr. Chipman's conservatism. I want to call attention to an excellent monograph on focal infections by Duke, which is just off the press. In it you will find a lot of information on many obscure points. Of course we are interested in focal infection mainly from a cutaneous viewpoint. Recently, in an aged man, suffering from chronic pemphigus, we found eleven apical abscesses; after these had been eradicated and the patient's mouth thoroughly cleaned up, the skin lesions promptly disappeared under the use of simple, soothing applications, and there has been no recurrence during a period of several weeks. In my opinion, all cases of discoverable focal infection should receive prompt attention, even though there is no traceable connection between them and the disease for the relief of which the physician is consulted. In acne, particularly, you will find that the removal of a pair of badly infected tonsils will often prove a long step toward bringing about the cure of the cutaneous disorder.

Dr. King Smith, Toronto: The procedure now in force in the Army affords a good opportunity to see these cases. Every man in the hospital in France and in other places has his teeth examined. This is a routine examination made by the dental department, not the thorough examination with the roentgen ray. There is no class of men whose teeth are so bad as the British Tommy; he has pyorrhea and every other kind of trouble. In a hospital where 21,000 passed through, skin diseases were very rare, except for pus infections. The British Army probably had only one dentist to 1,000 men, whereas the American and Canadian armies have a dentist for every 500 men; so the teeth are being well looked after. With so much focal infection of the teeth I was interested to see so little skin infection. As to infection from suppurating sinuses, throughout the Canadian Army last year a large percentage of returned men had a dermatitis resembling an eczema. We began to examine them by different methods and soon it was noticed that practically all had returned on one hospital ship. Word came that every suppurating case coming into that port must have swabs taken and a bacteriologic examination made. It turned out to be a diphtheritic infection. There was no diphtheria on the ship, but all these cases were due to this bacillus, when there had been no sign of diphtheria for months, and all came from this one hospital ship.

Dr. John E. Lane, New Haven, Conn.: I am a firm believer in the clean mouth and in the removal of pus wherever it may be found. However, I do not think that we yet have sufficient evidence for believing that focal infection is an etiologic factor in all the diseases that have been mentioned. It seems to me that in deciding the etiologic importance of focal infections a lot of rubbish must be cleared away before we get down to the productive soil of conclusive experiments. Focal infection does not always necessarily affect the general health. One important question is whether the infection is confined under enough pressure to cause absorption. The wall of an abscess is a very poor organ of absorption, but if it is confined and under pressure there undoubtedly will be some absorption though it is frequently difficult to decide whether this is taking place. It is evident that in many cases of pyorrhea with free drainage there is little or no absorption and no constitutional symptoms of absorption. All the patient is getting is pus and bacteria, which he swallows and digests, with health which is astonishingly good under such filthy conditions. A much better absorptive surface is offered by the tonsils than is found in pyorrhea. It is more difficult to determine the rôle played by apical abscesses. I am not at all convinced whether focal infection is or is not an etiologic factor in any of the conditions discussed. I am convinced that there is an etiologic relationship between focal infections, especially of the tonsils and of the teeth, and many of the arthritides.

Dr. Frederick G. Harris, Chicago: I am not yet convinced of the rôle that focal infection plays in the etiology of all these various dermatoses. If we assume that these infective foci contain any of possibly half a dozen different organisms, we find that these few micro-organisms can cause very many different diseases, varying in type from eczema to pemphigus and from lichen planus to dermatitis herpetiformis. I think it is time for us to get down to true scientific work. Why have not the various organisms been isolated and identified? Let us see if the same disease supposedly due to apical abscess shows the same bacteria as the abscess. Then, let us study the metabolic products of these bacteria both chemically and in their effect on the skin. It seems to me that focal infection is an accessory after the fact and not before.

Dr. M. Scholtz, Cincinnati: A sufficient number of cases has been reported to establish firmly the causative relationship of focal infection to skin diseases. However, focal infection should not be considered as the sole etiologic factor in all cases. Other pathogenic factors should be considered in possible correlation, all working, as it were, in a vicious circle. For instance, focal infection may induce skin anaphylaxis due to proteids of bacteria or their toxins; this in its turn may affect the system of endocrine glands with a new train of symptoms. In regard to lichen planus, there is no question that some of the cases may be traced to focal infection, but why should we limit the sources of it to teeth and tonsils only? On the other hand, the fact that the patient improves after the removal of a focal infection does not always establish the causative relationship. The patient may get well simply because after a weakening or toxic effect of an infected focus had been removed, the system may regain vitality enough to combat other coexistent pathogenic factors which may be present in the case.

Dr. Everett S. Lain, Oklahoma City: I am still largely of the opinion that the field of focal infections in dermatology is quite limited. I have observed, as have Dr. Chipman and Dr. Ravitch, the various skin lesions in connection with focal infections in a casual way also, and have tried to follow one certain disease for several months, studying the cases carefully. Again, I want to stress what has already been said, that the mere passing on the mouth by the dentist is not at all confirmative, especially if that dentist is the one who has put the crowns on the teeth or done the bridgework. It is always more satisfactory to have the roentgenographic work done in one's own office than to depend on somebody else on account of the various angles which are needed for correct diagnosis. My experience with urticaria has not been positive in regard to focal infection. In lupus erythematosus I suggest that if every case is carefully noted I think we shall see that this disease also bears a very close relation to focal infection. With reference to zoster sometimes being caused by arsenic, that is an established fact, but could that not be an exacerbation due to the breaking up or scattering of these toxins, the same as we have seen in the secondary stages of syphilis after giving arsenic? The extraction of a tooth often lights up the trouble, as has been mentioned.

Dr. David Lieberthal, Chicago: I wish to call attention to the familial occurrence of lichen planus, which strongly suggests infection as a cause. There are about thirty cases on record which showed simultaneous appearance of the disease in two or more members of the same family. The theory of focal infection has created a great deal of enthusiasm and confusion and caused many patients to lose teeth unnecessarily. If methods could be devised to drain pus foci around teeth without sacrificing the latter, no harm would be done nor adverse criticism heard to focal infection around teeth being offered as an etiologic factor.

Dr. J. S. Eisenstaedt, Chicago: In the discussion of lichen planus I am traveling on thin ice, for the reason that my results are less favorable in the treatment of lichen planus than any other disease. I have treated lichen planus in professional wrestlers, who are not of a nervous type. Several years ago I had patients whose parents had syphilis. I thought I saw a relation, but the patients had negative Wassermann reaction and it was probably only a coincidence. I have obtained results by giving mercury internally or by injection; I have also had results from arsenic—Fowler's solution, or sodium cacodylate, or sodium arsenate, and then again other cases did not respond to that treatment. Among other cases seen recently was a case in which the teeth were very bad and I had them removed. Afterward I used mercury and arsenic, but the improvement was very slow. I believe that lichen planus is still mysterious as regards its etiology, and equally so as regards the prognosis from the usual types of therapy.

Dr. K. A. Zurawsky, Chicago: Dermatologists have been very unjustly accused of splitting hairs regarding the classification of diseases, and now we are going to the other extreme and generalizing everything under one head. I would like to make a few objections. In the first place, to say in the twentieth century and the present status of dermatology that certain diseases are due to "focal infection" without stating what that infection is, is bearing a little bit too hard on one's credulity and powers of imagination. There can be and there are some skin diseases which are due to infections; but we cannot expect that the cleaning out of an apical abscess or the taking out of the tonsils will remove all the causes of the half-dozen or dozen, or two or three dozen different diseases. Our friends, the dentists, who have started so much of the talk about focal infection, have given us the idea about focal infection, but have not told us of what that infection consisted. They have told us of the staphylococcus and streptococcus and other bacteria, but have never isolated any one of them, and until they do we should not talk of focal infection as a definite factor. Dr. Scholtz mentioned some of the ductless gland disorders that might be considered as the cause of local reaction. I think anything of this kind may exaggerate the patient's condition, whatever may be the etiologic factor.

Dr. John H. Stokes, Rochester, Minn.: Focal infection certainly impresses one as having been the stamping ground of the *post hoc propter hoc* type of clinician. The conservativeness of Drs. Ravitch and Chipman's papers is therefore eminently praiseworthy. Much experimental work is still needed before any of us can feel that the subject has passed beyond the realm of speculation. The mere fact that a lesion clears up following the removal of an abscessed tooth or the use of a vaccine is not yet to be accepted as a demonstration of the causal relation of the abscess or the specificity of the vaccine therapy. Speaking purely as a clinician, I have been much impressed by the apparent relationship between the foci of pyogenic infection in the teeth and tonsils and the generalized exfoliative type of dermatitis. I think a similar type of relationship may exist between pemphigoid eruptions and foci of infection. Several of my cases have seemed to respond exceptionally well to measures directed at a definite focus. I have even seen cases of alopecia areata come on abruptly following unintelligent dentistry and clear up after the removal of abscessed teeth. It must be obvious to any one with even a modicum of critical faculty that argument of this type does not justify sweeping statements at the present time.

Dr. Walter J. Heimann, New York: I have seen some remarkable cases that have cleared up in the same way that Dr. Stokes has mentioned. There is something about focal infection, but what? We are talking about it as being the etiology of skin diseases of a certain type. Everybody here has said that it is not. It may be a contributing factor, and we might look for the prostate gland, the fallopian tubes, the appendix, etc. I protest against the classification of diseases furnished by Dr. Lain. We know that rosacea is due either to gastrointestinal disturbance or to disturbance of the internal organs. This has been proved definitely. As to lupus erythematosus, while we do not know what it is, I am perfectly willing to concede that some cases may be due to focal infection, whatever that may be. I must enter a protest, however, against herpes zoster. We know that that is a definite clinical entity. A man has one attack and is immune. After the herpes zoster has disappeared the focal infection remains. Is it possible for the etiologic factor to cause a disease, the disease disappear and the etiologic factor remain? I think that is one of the greatest absurdities, and I wish that sort of reasoning could be eliminated from scientific discussions.

Dr. Michael L. Ravitch, Louisville, Ky.: I have not changed my opinion in the least. I am very conservative about focal infection and I do not believe that so many dermatologic cases are due to focal infections. I am in the middle of the road and trying to learn the true facts.

Dr. Ernest D. Chipman, San Francisco: We seem to be in the process of being swept by a wave of skepticism. Dr. Harris seems to feel that we should have a lot of experimental evidence in support of certain facts. If a man with diabetes is thirsty, you do not have to go to the laboratory to prove it. If a patient has a tapeworm, we need not go to the laboratory to know that he is hungry. I wish you to consider the connection of focal infection. I do not like the attitude of *laissez faire* in connection with our treatment of skin diseases. I submit that it is time to make an effort to do something constructive. If we cannot support our facts in a clinical way, let us at least do a little reasoning. I do not subscribe to Dr. Heimann's remarks regarding herpes zoster. Ample work has been done there. If one will read the work of Rosenow and Billings he will find that the same kind of organisms have been found in these lesions as in the nerves. It seems to me that if anything has been proved it is the connection between herpes zoster and erythema nodosum. A more extensive study may change my opinion, but at present, it is sure, we cannot ignore it. If we do, it is like an ostrich putting its head in the sand.

Dr. Ravitch spoke as if I was claiming that psoriasis was caused by focal infection, which was not the case. A year ago I reported seven cases of psoriasis that had a focal infection. I gave that simply for what it was worth. Since then I have had a case of psoriasis in which we found two abscessed teeth. They were extracted, the external treatment remained the same and the disorder cleared up. Within a month's time he had a recurrence. That did not square with the fact. The patient said he was sure he still had trouble with the teeth and another examination showed that this was the case. I do not say that psoriasis is caused by focal infection, but in these cases, if the patient has pus which is being absorbed slowly, or which is confined, we do not do our best for that patient if we ignore it. I think we are all agreed that we should do our best for our patients in every way.

As to lichen planus, I am not claiming that focal infection is a definite etiologic factor in this disease, but that it has been present in all the cases that I have seen.

ROENTGENOGRAPHIC STUDIES OF TISSUES INVOLVED IN CHRONIC MOUTH INFECTIONS *

ARTHUR D. BLACK, A.M., M.D., D.D.S.
CHICAGO

In a paper[1] presented before this section at the New York meeting last year there was included a tabulation covering a critical examination of 3,000 roentgenographic films of the teeth and adjacent bone of the mouths of 300 adults. During the past year these studies have been continued with results that very closely parallel the previous figures. The present tabulation, which includes that of last year, covers 600 roentgenographic mouth examinations, for each of which ten small films were made—a total of 6,000 films.[2]

The object of this study is primarily to determine as nearly as possible the average percentage of chronic mouth infections, which are of two types: (1) those that begin with inflammations of the gingivae and progress along the side of the root toward the apex, destroying the peridental membrane and adjacent alveolar process—chronic suppurative pericementitis; (2) those which, subsequent to the death of the pulp of the tooth, cause a destruction of the bone about the apex of the root—chronic alveolar abscess. Secondary to the foregoing, other data are being compiled, such as the existing relationship between these mouth infections and the general health, the number of teeth present at various ages, the number of teeth having root fillings, notations as to whether the root fillings are good or poor, and the frequency of alveolar abscess about the apexes of well filled and poorly filled roots. These studies are therefore considered to be of fundamental importance from two points of view: (1) that of chronic mouth infections as a cause of systemic disease, and (2) that of the dentist's technic in pulp treatment and root filling in relation to the occurrence of alveolar abscess.

---

* Read before the Section on Stomatology at the Sixty-Ninth Annual Session of the American Medical Association, Chicago, June, 1918.

[1] Black, A. D.: Roentgenographic and Microscopic Studies of Tissues Involved in Chronic Mouth Infections, The Journal A. M. A., Aug. 25, 1917, pp. 599-602.

[2] The 6,000 films, mounted, were exhibited in connection with the presentation of this paper.

An effort has been made to take roentgenograms of the mouths of persons as we meet them on the street, that is, without previous inquiry as to the condition of their mouths or their health, in order that our figures may represent average conditions. The 600 persons included in the tabulation consist of about 300 dental students, about fifty Dental and Medical Reserve Corps officers, about fifty of my own patients, and patients applying for dental service at Northwestern University Dental School. It is believed that the figures represent very close to average conditions for persons of less than 40 years of age, but the number of infective foci in persons past 40 is doubtless too high, because there are included a few who presented themselves because of systemic conditions that called for mouth examination.

Of the 600 adults examined, 78 per cent. are shown by the roentgenograms to have definite areas of bone destruction about the teeth. If we make every possible allowance for variations from the average which these 600 cases may represent, the fact remains that a high percentage of adults have chronic infections involving the maxillary bones. With our present knowledge of focal infections in relation to systemic disease, these mouth conditions constitute a serious menace to the health-producing power and longevity of the people.

AREAS OF CHRONIC INFECTION

The accompanying tabulation records areas of chronic infection about the teeth, in 57 per cent. of persons aged from 20 to 24, 64 per cent. aged from 25 to 29, 88 per cent. aged from 30 to 39, 90 per cent. aged from 40 to 49 and 98 per cent. aged 50 or more. As previously mentioned, the percentages for persons past 40 are too high because of the fact that a number of those included in the tabulation presented themselves on account of their general physical condition. Attention is also called to the fact that a considerable number of persons past 40 who are edentulous are also free from these infections. None of these were included in this study.

The areas of destroyed bone are given in two groups, under the headings "peridental infections" and "alveolar abscess." The term "peridental infections" is used here to cover all areas of bone destroyed along the sides of the roots of the teeth, from suppurations beginning in the gingivae. The term "alveolar abscess" covers all areas of bone destroyed at the apexes of roots, subsequent to the death of the pulps of the teeth.

The peridental infections are very seldom found in the mouths of persons of less than 20 years. They are to be considered as lesions of adult life only, which are more frequent with advancing years. For the group between the ages of 20 and 24, 13 per cent. had infections of this type; those aged from 25 to 29, 29 per cent.; those aged from 30 to 39, 68 per cent.; those aged from 40 to 49, 77 per cent.; those aged 50 or more, 88 per cent. These percentages alone do not tell the full story, as in addition to the increase in the number of persons with advancing years, there is also an increase in the number of areas per person, from four per person of those affected between the ages of 20 and 24 to ten per person in those aged 50 or more.

Alveolar abscesses are found in the mouths of persons of all ages. It would be expected that the number would increase with age, except for the fact that the number of abscessed teeth extracted serves to maintain a balance. In the present tabulation for persons aged from 20 to 24, there are recorded 52 per cent. who have abscessed teeth; for those aged from 25 to 29, 51 per cent.; for those from 30 to 39, 63 per cent.; for those from 40 to 49, 59 per cent.; for those of 50 or more, 50 per cent. The number of abscesses per person does not vary much with age, the average being 2.6 per mouth for those aged from 20 to 24 having abscesses, and the same for those of 50 or more. The lowest was 2.2 abscesses per person for those between the ages of 30 and 39. It is very interesting to note that last year's tabulation of 300 persons showed 59 per cent. with alveolar abscess, while for the 300 added this year only 41 per cent. had alveolar abscess. It is believed that this difference represents in some measure the better realization of the danger of these infections to health, with the result that a larger number of infected teeth have been extracted. No attempt has as yet been made to determine the percentage of abscesses in the mouths of persons of less than 20 years of age.

RESULTS OF QUESTIONNAIRE

It was not practicable to make thorough physical examinations of these patients, and only a limited number of reports of such examinations were obtainable. The effort was therefore made to secure by a questionnaire the best possible information as to the physical condition. Inquiry was made as to enlarged finger joints, muscles or joints which were occasionally painful, condition of the nose and throat, inflammation of eyes, attacks of appendicitis, etc. It is appreciated that this information is not very reliable, as it does no more than give a general idea of the health of the persons examined. Of the 501 included in the questionnaire, 363 are reported as entirely negative as to secondary systemic disorders, seventy-two complained of occasional muscular or joint symptoms, and sixty-six reported well defined cases of arthritis, nephritis, appendicitis, etc. Forty-two, of the last group of sixty-six, were persons of 40 years or older and a considerable number of these presented themselves because of their physical condition. None were hospital cases. The principal value which these figures on systemic conditions give to the tabulation is in showing that the large majority of those examined were in good health, from which fact we may conclude that the number of areas of infection reported are not likely to be far astray in the establishment of average figures, with the exception, already noted, of persons past 40.

The average number of teeth per person is an indication that the mouths have probably had average care by both patient and dentist. It is noted that for the 411 persons in the three groups covering ages from 20 to 39, there is an average of twenty-eight teeth. As the third molars are not constant in development, there is an average loss of less than four teeth per person up to 39 years.

ROOT CANAL FILLINGS

A feature of this tabulation of especial interest to dentists is the occurrence of alveolar abscess in relation to good and to poor root canal fillings. For this study the roots of the teeth were divided into two groups: those having large canals and those having small canals. This division was made because of the differences in technic required. The upper central incisor, cuspid, second bicuspid, and lingual roots of molars, the lower cuspid, the first and second bicuspids, and the distal roots of the molars were classed as having large canals. The upper lateral incisor, first bicuspid and buccal roots of molars, and the lower incisors and mesial roots of molars were classed as having small canals.

TABULATION FROM 6,000 ROENTGENOGRAPHIC FILMS OF TEETH AND ADJACENT BONE IN MOUTHS OF 600 ADULTS*

Age	Number	Systemic Symptoms				Average number teeth per person	Peridental Infections			Alveolar Abscess			Summary		Root Fillings				Large Canals				Small Canals				Alveolar Abscesses

Large Canals: Upper—central incisor, cuspid, second bicuspid, lingual roots of molars; lower—cuspid, first bicuspid, second bicuspid, distal roots of molars.

Small Canals: Upper—lateral incisor, first bicuspid, buccal roots of molars; lower—incisors, mesial roots of molars.

SUMMARY OF ABSCESSES IN RELATION TO ROOT FILLINGS

			Number Abscessed	
Good root fillings, large canals	343		31	
Good root fillings, small canals	184		19	
		527		50
Poor root fillings, large canals	570		356	
Poor root fillings, small canals	413		271	
		983		627
		1,510		677

* Percentage of abscesses for all root fillings, 45; for good root fillings, 9; for poor root fillings, 63.

The figures given in this tabulation are believed to be very close to average figures for persons under 40; for older persons they doubtless show a higher percentage of infection than the average.

The roentgenograms showed 1,695 teeth with root fillings. This is 10 per cent. of all of the teeth in the mouths of the persons examined. Of these teeth, 344 were not included in the special study of root fillings, because the shadows were not sufficiently clear for positive reading. Each root of multirooted teeth was counted separately. There were recorded a total of 343 good root fillings in large canals, of which thirty-one were abscessed, and 570 poor root fillings in large canals, of which 356 were abscessed. For the small canals, there were 184 well filled, of which nineteen were abscessed, 413 poorly filled, of which 271 were abscessed. This gives only 9 per cent. abscessed of all teeth having good root fillings, and 63 per cent. abscessed of all teeth having poor root fillings. Doubtless some in both groups were abscessed before the root fillings were made. It seems that no better argument could be found to induce dentists to be more painstaking in their root filling technic, for here is the opportunity to reduce the total of alveolar abscesses to about one fifth of the present number—an effort very well worth while.

It should be stated that we have been very liberal in classifying these root fillings; if we have erred it has been by placing an excessive number in the "good" columns. It is appreciated that it is not always possible to determine the condition of a root filling by examination of a roentgenogram. Fillings were classed as good if the root apex was apparently filled, or, in those cases in which the root filling did not reach to the apex, if no canal was discernible beyond the root filling. By this plan, all questionable fillings were given the benefit of any doubt.

CHANGES IN DENTAL PRACTICE

The effect of the study of these cases is well shown by the changes that have been noted in the clinic of Northwestern University Dental School. The roentgenographic service has been increased several fold as compared with a few years ago, a total of more than 17,000 films having been made during the past year. In the same period nearly 24,000 teeth were extracted, and the number of artificial crowns and bridges much reduced, while there has been a corresponding increase in the number of artificial dentures made for patients. This is an expression of the changes in dental practice throughout the country. A constantly increasing number of dentists are coming to realize that it is their positive duty to free the mouths of patients from infection, even though this requires the extraction of a number of teeth. But what is of much more importance, there is a determined effort on the part of many to use every possible means of preventing the occurrence of these chronic mouth infections, and those who have seriously undertaken to do so are meeting with a large measure of success. This is preventive dentistry that is worth while, for it is cutting off at the source much systemic disease.

ABSTRACT OF DISCUSSION

Dr. Eugene S. Talbot, Chicago: Dr. Black speaks of so many cases of root filling and then so many abscesses. I would like to have him tell how he knows these are abscesses. My researches have shown that we must classify, that we must know exactly what takes place at the roots of the tooth. Many of these cases that are called abscesses are not abscesses. They are simply absorptions. In all these experiments that I have been doing the last three or four years, with the microscope, destroying pulps of teeth and then immediately conducting the different drugs that we use through the ends of the roots of the teeth, this sequence invariably takes place. The irritation produces an absorption of the alveolar process. It depends on the amount of the irritation as to where that absorption stops. If it is a slight irritation, the absorption of bone will take place and fibrous tissue will remain around the end of the root of that tooth. That absorption may or may not be very extensive. If the irritation is more severe than what I have just mentioned, the fibrous tissue will be destroyed around a certain area, and that absorption and destruction of fibrous tissue takes on the appearance of what is called an abscess under the roentgen ray. I have noticed that many cases which presented conditions that were considered abscesses were not abscesses, but simply absorptions of the alveolar processes and roots and destruction of the peridental membrane at the end of the root of the tooth. If the irritation is still greater, with infection, so that even the fibrous tissue is destroyed, an abscess will form. There are three conditions or stages which we must understand and classify by the roentgen ray. I have not been able to classify these with the roentgen ray. We must first examine the case with absorption in order to show the three different conditions that take place. I want Dr. Black to explain these three different conditions, if he can, and why he calls all these cases abscesses. The other condition is where the fibrous tissue will remain after the absorption of bone. The next is where the irritation and infection are so great that an abscess will form. First, there is absorption of bone and root. The peridental membrane still remains because there is not sufficient irritation to produce a destruction of the peridental membrane and fibrous tissue. Second, the peridental membrane and fibrous tissue are destroyed without an abscess forming. Third, the fibrous tissue remains around the root of the tooth and an abscess forms in this fibrous tissue and remains after absorption of bone has taken place. These are the three actual conditions that occur and are seen with the microscope.

Dr. Thomas L. Gilmer, Chicago: I am in accord with Dr. Talbot's statement that there is in some instances, indication of absorption of the process when no infection exists. After examining roentgenograms, we are sometimes left in doubt, whether abscesses exist or not. There may be a very limited area of bone destruction followed by a thickening of the pericementum when no infection exists. I am of the opinion, however, that in the majority of these cases the areas are infected. My reason for this belief was strengthened by my study of the bacteriology of alveolar abscess. I extracted a large number of pulpless teeth and secured the *Streptococcus viridans* from almost all cases, when the roentgenogram showed rarified areas. Alveolar abscess, when some of the apical peridental membrane has been destroyed, may be cured temporarily by sterilization of the root canal, but it is for a very limited period, because there will be reinfection sooner or later through the organisms being carried to the dead cementum by the blood stream.

Dr. Arthur Zentler, New York: Whether or not the roentgenogram can be relied on to tell the condition present at the apical end of a root is not established. While some doubt has been expressed here as to whether there is or is not an abscess when the roentgenogram indicates absorption, there remains to be shown whether when the roentgenogram does not show absorption, that there actually is no pathology. I have been impressed with this unreliability. Experiments which I carried on to establish whether conservative (electrolytic) treatment is sufficient to cure pathologic conditions at the apexes of roots, or whether apecoectomy is necessary to obliterate the infection, have resulted in the following: First, teeth which were treated conservatively and which in the roentgenogram showed no absorption, were apecoectomized several months after treatment and the cultures have yielded streptococci. Second, the same areas were cultured four or six months later under the same condition as for doing a root amputation, and although the roentgenogram indicated absorption (due to repeated surgical interference), cultures made from scrapings yielded no bacterial growth. To my mind this shows that lack of absorption in the roentgenogram does not indicate sterility, nor does the presence of absorption indicate infection at the end or around the root of the tooth.

Dr. Frederick B. Moorehead, Chicago: The work that Dr. Black has done in his report is reassuring in that it confirms the fundamental things we have believed for some time. I examined 500 cases at the Presbyterian Hospital, Chicago, and reported my results to this section two years ago. My findings were essentially the same as those reported by Dr. Black. Considerable experience and study is required in the interpretation of roentgen films of the jaws, and even to the experienced there will be surprises now and then in the amount of pathology that will be found clinically which did not appear in the film. It must be borne in mind always that the roentgen ray is a relative agent, and while it is the most important factor in diagnosis, it requires experienced interpretation. The fact that one frequently finds more pathology on the removal of a tooth than is indicated by the roentgen ray should make us very careful in concluding from a roentgenogram that a tooth is safe.

As Dr. Gilmer has suggested, there are cases in which it is very difficult to differentiate between a dangerous focus and one that probably is not dangerous. These difficult cases, however, are more or less limited in number and the majority of films indicate conditions about which we may be more or less dogmatic. We found one very striking thing in our patients in the Presbyterian Hospital in noting that there was not a great deal of difference between the ward patient and the private patient in the number of mouth involvements. This is probably due to the fact that the poor people have troublesome teeth extracted while those of means have root canal treatment. We must all become convinced of the danger of chronic infection about the jaws and the necessity for the removal of all types of infection.

Dr. Chalmers J. Lyons, Ann Arbor, Mich.: We must not overlook the mistake that both the dental and medical professions are making today of relying wholly on roentgenograms. I am very much interested in Dr. Talbot's remarks that we should not consider the roentgenographic evidence alone. It is simply one method of making a diagnosis and I am wondering if in the report Dr. Black has made that some distinction might not be made between what he calls an abscess of the roots with poorly filled canals and an abscess of a root with well-filled canals. While the roentgenographic evidence would admit of some error, without a complete history of that particular operation, I do not see how he can classify a tooth with a perfectly or well-filled canal having an area of absorption as an abscess. If that is true, if they can be so classified, then our whole root canal work is in vain.

Dr. William C. Fisher, New York: I am very glad to hear one part of Dr. Black's report in which he studies the good and bad root fillings in order to differentiate them in reading his roentgenograms. He classifies them as cases with good root filling and those roots in which the filling did not go to the apex. This is the first time that I have seen or heard any one attempt to make that statement and I am very glad that Dr. Black has made it, because in that one point

I consider great advance has been made. Dr. Zentler's work is a step in the right direction, especially the manner in which he has investigated the bacteriologic findings. As Dr. Talbot and Dr. Lyons brought out, can we tell whether these areas that we speak of off-hand from roentgen-ray evidence as abscesses are really abscesses unless we have checked up this evidence with other work? Dr. Moorehead said the more we read roentgenograms the better are we able to interpret these facts. No mention has been made of the particular bacteria found other than what is usually found in these abscessed areas. It is a question in my mind as to just how much the system can stand in the way of the normal presence of *Streptococcus viridans* or, as Dr. Moorehead said, in the safe and dangerous zones of infection.

Dr. Arthur D. Black, Chicago: I endeavored to present certain conditions that were shown by examination of 6,000 roentgenograms, and I believe I qualified that by saying that I presented tabulations of the areas of destruction of bone. Then I stated further that in order to simplify the presentation I called one group peridental destruction, and the other apical destruction. The main point I desire to impress is that over 75 per cent. of the people over 20 have destruction of bone about the roots of teeth.

I would base my judgment in deciding on the treatment of any case showing an area of destruction about the root of the tooth, on the extent of the detachment of the peridental membrane from the surface of the root. If the studies of the histologic function and pathologic changes which take place in these tissues are worth anything to us at all, they certainly tell us that where the peridental membrane has been detached and that detachment has been maintained for a time, there will not be a regrowth of this tissue. If there is a hole in the bone about the end of the root of the tooth, showing that the peridental membrane has been destroyed, then I would not bother to determine whether the area is infected or not, as it would not make a particle of difference in the treatment. If the area is not infected today it may be infected through the circulation tomorrow. I have no doubt that a considerable number of these cases go along for a long time without infection, but they certainly present ideal conditions for reinfection. Granting for the moment that by the use of drugs such an area may be rendered sterile, there could not be more than a very temporary advantage because there is no probability of reattachment of tissues to the root of the tooth. When the roentgenogram shows an area of bone destroyed immediately about the surface of the root, I believe it should be treated as though it were an abscess whether there is any infection or not.

There can be no question that the number of persons having infections of the bones about the teeth is very much larger than it ought to be. It must be less in the future, and the burden of reducing it is on the dental profession. At the same time, we must remind the members of the medical profession that there are many other regions besides the mouth in which original foci of infection occur. When we come to realize that 75 per cent. of adults have some infection of the maxillary bones, it seems that three out of every four persons, who go to the physician complaining of some systemic infection, have one or more of these areas in their mouths. I am afraid that too many physicians are jumping at the conclusion that the teeth are the source of the trouble, without making a thorough investigation of other regions, such as the nose and throat, the sinuses of the head, the mastoid, the gallbladder, the genito-urinary tract, etc.

Every adult who comes to us should have a complete roentgenographic examination of the mouth. When each dentist takes on himself the responsibility of knowing that the mouths of his patients are free from infection, he will have made real progress in the prevention of systemic disease.

Dr. William C. Fisher: Do you believe that in any dead tooth perfectly filled or imperfectly filled you have this area whether it has been treated surgically or not?

Dr. Arthur D. Black: It does not necessarily follow that because the pulp of the tooth dies the bone about the apex of the root will be infected. That is the natural thing to happen, but I feel quite satisfied that it does not always happen, otherwise practically every tooth with a dead pulp should be extracted. We are requiring that a roentgenogram be made of every tooth that has a dead pulp before treatment is undertaken. We are getting many films of cases with dead pulps which show no destruction of tissue about the apex of the root. It is a question of following these up for a number of years by roentgenographic examination. My judgment is that there are many cases in which there is no infection beyond the apex of the root.

MALARIA ENDEMICITY OF THE RICE DISTRICTS OF LOUISIANA AND ARKANSAS

WITH SOME OBSERVATIONS ON TYPES OF MOSQUITOES BREEDING THEREIN

J. C. GEIGER, M.D., W. C. PURDY, M.S.
AND
LOU INA BATES, B.S.
Assistant Epidemiologist, Biologist and Microscopist, Respectively, United States Public Health Service.
LONOKE, ARK.

The selection of a site for the establishment of an aviation field amid the rice fields of Arkansas offered an unusual opportunity for the study of control methods for malaria and types of mosquitoes found breeding in this environment. We realized that the control methods must of necessity be of a varied character, but agreed that the control of the human carrier along with the mechanical protection of good screening were most important within the limits of mosquito flight. Therefore the initial step was a sanitary survey to correlate all methods in the 3 mile zone designated as the extracantonment zone, Eberts Field, Lonoke, Ark. This included the town of Lonoke, and work was begun in January, 1918. In addition, absolute control of the breeding of mosquitoes outside of the rice fields was to be sought. The area within which mosquito control measures were taken comprised approximately 12 square miles, the center of which is the aviation field and the town of Lonoke. In the west and south, in this district, rice is grown, the area under cultivation being 2 square miles. From the buildings of the aviation field, the first rice fields are at a distance of 1 mile on one side and three-fourths mile on the other, and just 1,500 feet from the field limits. Rice fields adjoin the town

MALARIA ENDEMICITY

The history of chills and fever for the previous summer gave a malaria incidence index which affords probable important data for the extracantonment zone, Eberts Field, and offers an interesting parallel to similar observations and the data obtained in the rice fields of Louisiana. The total incidence of malaria from history alone in the combined rural and town population in both the Louisiana and Arkansas districts is, curiously, the same, approximately 29 per cent. A slide endemic index (thick smears) taken in January, April and May gave remarkably low percentage results, as shown in the accompanying table.

Technic of Staining.—1. To 100 c.c. of ethyl alcohol, 1.3 c.c. of hydrochloric acid are added. The slides are placed in this solution for three or four hours, that is, until they become a ground glass color. They are rinsed in running water for five minutes. The time in acid is relatively dependent on the age of the blood smear.

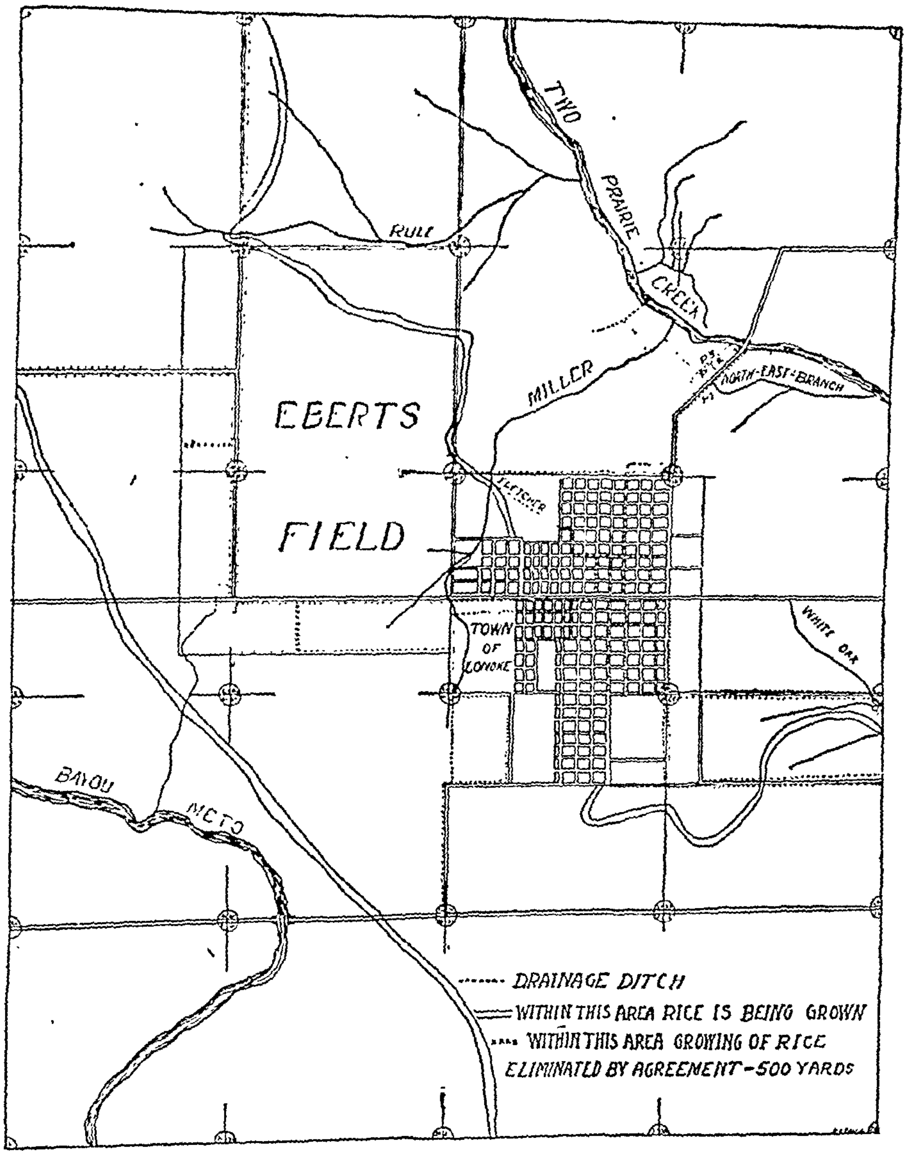
2. (*a*) To 100 c.c. of distilled water, 3 c.c. of 1 per cent. polychromethylene blue solution are added. The slides are placed in this solution for four minutes and then rinsed in running water for one minute.

(*b*) To 100 c.c. of distilled water, 2.6 c.c. of 3 per cent. eosin solution are added. The slides are placed in this for one minute, and then rinsed in running water for one minute.

(*c*) The slides are dipped in the polychromethylene blue solution for one minute, and then rinsed in running water for one minute, dried and examined.

Meyer[1] reports almost a negative endemic index taken in the spring months in California. Kelly and Geiger,[2] working practically in the same district but in September, report an index of 4.7. When one considers the number of persons in the rice districts under our investigation giving a history of chills and fever for the previous summer and the small number proved positive on microscopic examination (thick smears), then one can assume that there are several factors to be considered:

1. In an endemic index taken in the spring months, the number of carriers discovered will probably be small. An endemic index varying so much at different seasons is not indicative of true malaria conditions and never should be judged accordingly. Nevertheless, the discovery of carriers, though small, is evidently a potent factor in the malaria rate for the coming summer. This is borne out by the fact that up to Sept. 1, 1918, no new cases of malaria have been reported in the extracantonment zone, Eberts Field. Therefore the value of an endemic index is obviously limited to a human control measure in this investigation.



Extracantonment zone, Eberts Field.

2. A history incidence index for the previous summer is not reliable if the microscopic index (thick smears) is to be taken as indicative of true malaria conditions, though several factors may influence the results, namely, the use of quinin as a preventive for common colds in winter and the constant use of chill tonics through the winter months, which is true of the Lonoke district from daily observations of druggist sales since Jan. 1, 1918.

3. The large number of patients having malaria, as judged by the history incidence index, were completely cured of the disease by attending physicians. We know this not to be true, the diagnosis never being checked microscopically or the case followed to completion.

4. Temperature and season evidently have an effect on the malaria carrier rate.

The different results in the January and May indexes on the same persons illustrate the intermittence of the malaria carrier along with the seasonal variance even when we consider the possibility of our missing the plasmodia on examination. This point is forcibly brought out by the fact that three schoolchildren whose blood was found negative in both indexes were proved positive carriers after having taken their initial dose of typhoid vaccine, the chill and rise in temperature almost immediately following. Two boys, aged 8 and 10 years, respectively, who gave a history of chills and fever for three previous summers with a gradual cessation of active symptoms and whose blood smear was negative in the January index, were proved positive in the May index. Their blood examined daily for one month, no quinin being given, gave in one only two additional positive results and three in the other. The plasmodia in both instances could be considered very resistant to the stain.

---

[2] Kelly, F. L., and Geiger, J. C.: Endemic Index of Malaria in the Northern Sacramento Valley, California, The Journal A. M. A., May 5, 1917, p. 1319.

Since this investigation started, there have been reported by physicians for Lonoke County 642 cases of malaria with one death. No reports are available or reliable for the previous years, and this number is probably indicative of true conditions. For instance, in the same period in the past year seventeen deaths (eighteen for the entire year) were reported as being due to malaria. The mosquito control, though perfect since March, 1918, in three other areas in Lonoke County and partially so in the extracantonment zone because of rice fields, cannot be considered a factor in reducing the number of deaths because of its own obvious limitations to small areas, even though these are centers of population. The immediate and only cause in the reduction of deaths from malaria is probably a better and more complete diagnosis of the patient's illness by the physician, the intensive educational campaign carried on here having its maximum effect.

MOSQUITO OBSERVATIONS

For purpose of comparison, the following observations made in Louisiana in the Gueydan District in 1917 are given:

Observations were begun, June 1. On large rice fields, ten days after irrigation, mosquitoes were breeding in public health quantities.

Successive catches in June showed only *Anopheles crucians* and *A. punctipennis,* the former about twice as abundant as the latter. *A. quadrimaculatus* was first found in the latter part of June, and by July 10 had superseded all others. These observations as to breeding were checked by catches of imagos in nearby barns. During the latter part of June and the first of July, salt water entered the Louisiana canals. In a field containing this water, showing from 12 to 23 grains of salt per gallon, *A. crucians* was the only anophelene present.

EXTRACANTONMENT ZONE, ARKANSAS

Ditching and oiling had established practically a perfect control of mosquito breeding early in March. This control was maintained continuously in the extracantonment zone. The observations by months may be thus summarized:

February—*A. punctipennis* was observed biting, February 26, in Lonoke and in the aviation field. Two females and three males were captured. No breeding was found.

March.—No breeding of *Anopheles* was found; no imagos were seen.

April.—Two imagos of *A. quadrimaculatus* were caught in town, April 17-20. *A. crucians* was breeding in rain barrels outside of town.

May.—There was a small amount of breeding (chiefly *A. quadrimaculatus*) in ditches. One imago was captured in a house. There was breeding of *A. quadrimaculatus* in moderate abundance outside the extracantonment zone.

June.—June 5-8, *A. quadrimaculatus* was breeding in moderate abundance in the rice fields about 1 mile from town. Imagos were abundant in nearby barns and were found biting in town, June 8-12. June 20, *A. quadrimaculatus* was again breeding in the same rice fields, and imagos again were numerous in nearby barns and found biting in town a few days later. One *A. punctipennis* was caught in town, June 25.

The early appearance of *A. punctipennis* (February 26) may be due to hibernation (1) of adults, (2) of larvae or pupae, or (3) from eggs laid early. It is worth while to note that temperatures were relatively high in the second week of February, the "mean" temperature varying from 48 to 66 F.; then colder for the third week (means, 26 to 54), and warmer again in the third week, when the mean temperature varied from 40 to 66, the highest single reading being 87 F., February 25.

A. quadrimaculatus has been the only anophelene found in public health quantities. Rice fields situated 1 mile from Lonoke and a greater distance from the aviation field were the only places within and over reasonable flight distance where breeding could be found at certain intervals. Several days following these observations large numbers of imagos were caught in nearby barns where none could be found previously, and simultaneous catches were made in houses in town and in the aviation field. Therefore the obvious maximal flight distance judged by these concomitant catches was more than a mile.

It is interesting to note that when water became "dead" on rice fields, through partial draining, or by stopping of pumps, *A. quadrimaculatus* was apparently superseded entirely by culex forms, though only an occasional culex could be found on this field when *A. quadrimaculatus* was abundant. Up to Sept. 1, 1918, no infected mosquitoes were found, though many were dissected.

Samples of wet mud from puddles and rice fields recently drained were examined for surviving larvae and pupae. The results were negative. In drained rice fields and puddles, water was found to remain in deep crayfish holes. These were pumped and examined for larvae. Five such samples were negative, and two contained numerous culex larvae.

CONCLUSIONS

1. The control of the human carrier plus the factor of good screening have, so far, made negligible the malaria incidence in a typical rice district. As it is not yet humanly possible to obtain absolute mosquito control in the rice fields, these measures are indispensable.

2. The persistent breeding of *Anopheles quadrimaculatus* in the rice fields and the repeatedly recorded "obvious flight distance" of this mosquito of more than a mile emphasize the necessity of the foregoing measures. The observation that culex superseded anophelenes in "dead" water in the rice fields deserves further study.

3. The positive indications of breeding in crayfish holes, which abound everywhere, is suggestive enough to offer a simple solution to the sudden appearance of large larvae or pupae in puddles after rains, which before were dry.

4. The history incidence index in two widely separated rice districts is the same. The incidence, though less than one would expect, is probably representative. The average incidence in schoolchildren taken as a unit invariably equaled that of the community as a whole, indicating strongly their availability for experimental index work and the obtaining of data.

DISINFECTION OF THE KNEE JOINT*

ROBERT B. COFIELD, M.D.
CINCINNATI

Whether in civil or military practice, it is generally conceded that septic infection of the knee joint is one of the most serious conditions that the surgeon can be called on to treat, endangering, as it does, both the future usefulness of the joint, and at times, the very life of the individual.

In civil experience we have formerly been led to a profound distrust of the ability of this particular articulation to deal with infective processes. In septic arthritis, an arthrotomy was usually advised and drainage tubes or wicks were inserted into the joint cavity, or through and through drainage was established and the tubes allowed to remain for at least a number of days. Besides producing an evil mechanical effect on the synovia and cartilages, the drainage material provided an ideal reservoir for the pabulum in which the organisms could multiply and travel from within outward, spreading infection to the para-articular structures, or from without inward, carrying secondary infection from the skin into the joint cavity.

The anatomic structure of the knee joint is such that when it is severely infected over its whole extent, drainage becomes a serious and difficult matter, and even though skilfully done, it is a most unsatisfactory procedure, often resulting in the tracking of the infection along the muscular and fascial planes, above or below the joint, with the accompanying dangers of septicopyemia and severe damage to the joint structures, resulting in ankylosis.

CONDITIONS NECESSARY FOR FAVORABLE RESULTS

The results achieved in the present war, in treating infected wounds of the knee by disinfection and immediate closure, have been the source of much surprise and satisfaction. Favorable results, however, with restoration of joint function, seem to depend on the observance of certain principles which are doubtless of equal importance in treating septic arthritis of autogenous origin:

1. The operation must be done early, before the spread of infection and the disorganization of the joint structures have had time to occur.
2. Thorough lavage of the infected and contaminated areas, followed by primary closure of the joint capsule, is essential.
3. Foreign bodies must not be allowed to remain within the joint cavity.
4. When drainage is used at all, it should be carried down to the capsule but not into the joint cavity.
5. Immobilization of the joint must be secured by adequate mechanical fixation.

In order for a surgeon to carry out these principles effectually, it is of the utmost importance that a diagnosis of suppurative arthritis be made early in the course of infection. This is not often difficult, since the joint involvement usually accompanies or follows a focal or general infection, originating elsewhere in the body, such as, gonorrhea, tonsillitis, otitis media, scarlet fever, pneumonia, etc.

This form of arthritis may be secondary to a serous synovitis or it may start without any obvious serous stage. The septic joint is often ushered in with a chill, the temperature is elevated, the capsule becomes distended with fluid, and the joint is inflamed and painful and is held in a semiflexed position by the spasmodically contracted muscles.

Every joint that shows evidence of inflammation and effusion, during the course of a focal or general infection or following it should be aspirated under strictly aseptic precautions for diagnostic purposes. The nature of the aspirated fluid will be a very definite guide as to the proper course to pursue.

The bacteriologic side of the investigation so often fails to reveal the presence of micro-organisms in the joint fluid, either in smears or cultures, that considered by itself, it carries little weight, and negative findings in this regard should not influence the course of our treatment.

The cytologic investigation of the joint fluid, however, is a distinct aid to the diagnosis, and at times will materially influence the prognosis, in joint effusions. A high percentage of polymorphonuclear leukocytes found in a sample of the aspirated fluid will afford positive evidence of a septic condition. The normal synovial fluid from the knee joint is acellular. Pus, which consists of practically 100 per cent. polymorphonuclear leukocytes, is a surgically visible sign that infection of the part has occurred and calls for prompt surgical intervention.

TECHNIC OF DISINFECTION

The technic which I have followed in disinfecting the knee joint is briefly as follows:

The knee is prepared the day previous to operation by being shaved and scrubbed and wrapped in sterile dressings. After the patient is anesthetized, the field of operation is further sterilized with benzin and iodin. An incision 1½ or 2 inches long is made parallel to the inner or outer border of the patella, extending into the joint cavity. If found desirable this incision may be extended to facilitate a more complete exploration of the joint. By means of a gravity syringe, placed high enough to give the stream considerable pressure, the joint cavity is now thoroughly flushed for fifteen or twenty minutes. Instead of using the sterile glass tip, commonly attached to the tubing leading from the container, it is better for the operator to use a soft rubber tip which may be inserted into the various recesses of the joint without the danger of injuring their delicate lining.

Various solutions have been used with success for disinfection of septic joints. Some operators even assert that the results do not depend on the nature of the solution employed, but rather that it is the thorough mechanical cleansing which is the important factor. However, since it has been shown that the synovia and cartilage withstand very well the active disinfecting agents, and since the pathogenic organisms are harbored within the synovia and para-articular tissues, and not in the joint cavity, I prefer to use an active disinfectant which possesses a penetrating as well as a cleansing action. Mercuric chlorid, 1:15,000, in salt solution, as suggested by Dr. Cotton of Boston, maintained at a temperature of about 115 F. and this followed by physiologic sodium chlorid solution, has proved very satisfactory.

Since the capacity of the synovial cavity of the knee joint reaches its maximum when the leg is flexed to an angle of about 25 degrees, and since the contents of some of the bursae communicating with the joint are most easily emptied when the limb is in a semiflexed position, it is very important that flexion and extension of the joint should be passively carried out while the cavity is being flushed. This will aid materially in ridding the joint of the necrotic material and pus that have accumulated in these various pouches. It is also advisable repeatedly to press the edges of the wound close about the tip of the syringe in order that the fluid may distend the joint capsule and penetrate and flush out its various recesses.

---

* Read before the Section on Orthopedic Surgery at the Sixty-Ninth Annual Session of the American Medical Association, Chicago, June, 1918.

The objects sought by arthrotomy and irrigation of the joint cavity are:

1. Relief of the intra-articular tension, which doubtless has a deleterious effect on the synovial membrane and cartilages through its interference with the circulation and the normal secretory function of the synovia.
2. The removal of the necrotic material which acts as a culture medium within the joint cavity. The nature of this material precludes its removal by means of the trocar or an aspirating syringe.
3. The cleansing and disinfecting action on the synovia, which aids it materially in regaining a normal function and renewing its fight against infection. The synovial membrane, like other serous membranes, has an enormous capacity for combating infection if it is in a fairly normal condition.

After disinfection, the capsule is closed with catgut sutures, and if a drain is used at all, it is placed outside the synovial membrane for the sole purpose of taking care of the extracapsular infection. The wound is closed in layers and the joint is thoroughly immobilized, preferably by a plaster-of-Paris spica including the foot.

A fenestra may be cut over the knee and if an increase in the inflammation and effusion should occur, aspiration may be repeated, depending on the nature of the fluid as to the future course of procedure. It is not frequent, however, that any further difficulty is encountered. The temperature and pain usually subside within a few days, and the joint gradually resumes a normal condition.

POSTOPERATIVE MEASURES

The limb is maintained in a position of physiologic rest until the wound is entirely healed and all signs of inflammation have disappeared. The patient is then given the privilege of active motion once or twice a day, depending on the sense of pain as a guide to the extent of movement. Later, gentle passive motion, along with heat and massage, will often hasten recovery, but at first the utmost gentleness is necessary in order to minimize the risk of exciting a recrudescence. The absence of signs of inflammation does not always assure the absence of pathogenic organisms, and well meant efforts to establish mobility may set up an active condition within the joint, if passive motion is applied too vigorously or begun too soon.

Should fibrous adhesions form, which we feel reasonably sure are periarticular, they may be broken down by forced manipulations, with the patient under full anesthesia, in order to secure complete muscular relaxation, thus permitting the movements to be carried sufficiently far in all directions.

Intra-articular adhesions are best treated by gradual correction by means of suitable mechanical appliance, since rough handling is followed by further damage to the joint structures and still greater limitation of movement within the articulation.

ABSTRACT OF DISCUSSION

Dr. Charles A. Parker, Chicago: The extremely important point of the paper is that immobilization of a joint is the greatest factor in the saving of mobility. In four or five years' experience in the Cook County Hospital I have never opened a knee joint for sepsis, and I think I have never punctured one. The intern sometimes does that for me, before I know it, and gets information, more or less complete. The fluid is usually sterile, as Dr. Cofield stated. During that time we never had a patient die from knee infection or the knee infection get worse. We have had bad knees, of course—tuberculous in type, or otherwise; but that does not mean that a septic knee should not be opened sometimes.

In regard to washing out the joint, I have had no experience with it. Any antiseptic is out of place in a joint. As to any antiseptic entering living membrane and killing bacteria between live cells and getting out again, leaving the bacteria dead and the cells alive, that would be a new and interesting experience.

Dr. John P. Lord, Omaha: There are infections and infections of the knee. The milder infections can be treated in various simple ways; but the more extreme and more malignant infections are very grave propositions. Unfortunately, we often see these cases after very destructive changes have taken place. Of course, it is our desire always to see them sooner, before irreparable damage has been done.

I wish to commend this paper. I think it is very safe to follow. Unfortunately, these conditions are too often attacked in a sort of by-guess and by-gosh fashion. Dr. Cofield has made a very valuable contribution to this subject, and dealt with it very rationally. His method of leaving the joint without foreign material in it is very important. I have felt that there is some advantage in a weak antisepsis. Perhaps the mechanical cleansing, the irrigation and relief of tension is the chief factor. It seems to me that we might learn something, also, from the recent technic of delayed primary sutures. I understood him to say that if we leave a vent, but not a drainage tube or gauze, merely leaving it sufficiently patulous for a suture, that will perhaps prevent the necessity of resorting to drainage. I think that this technic is too often neglected. We frequently leave the case with uphill drainage. If we have opened on the front, it is only reasonable that we turn the patient on his face and get the advantage of gravity. In the cases reported by Dr. Cofield, there may have been a large number of rather innocuous types of mild infection, which would go through their course without severe infection in any event. It requires a nicety in discrimination to determine whether more radical procedures may be necessary; but it seems to me that if we adopt the principles laid down by Dr. Cofield, and possibly supplement them, that it may be of advantage and we may save function in cases in which we have hitherto had a considerable number of stiff knees.

Dr. Albert H. Freiberg, Cincinnati: Perhaps, because so many knee joint infections are caused by gonorrhea, I am reminded of the opening sentence in Ricord's book on gonorrhea, written many years ago. He started his book in true dramatic French fashion by saying, "A gonorrhea begins; God only knows when it will end!" The same thing is true of joint infections, in a way. So many of them start in a quiet, harmless sort of fashion; but no one knows in the beginning where they are going to end. No one knows how far the vital structures of the joint are going to be damaged, or how serious the infection is going to prove. Of course, the very beginning is the time when surgical intervention can accomplish most for the patient. Over fifty years ago, in the absence of bacteriologic assistance, Volkmann described several types of joint infection, which he classified, according to the knowledge of the day, as catarrhal, suppurative and phlegmonous arthritis. A catarrhal arthritis was one that subsided without any intervention except rest. If the joint fluid were removed it was slightly turbid, but more or less serous in character. There were all gradations, from this to the frankly purulent material, which, of course, constituted the suppurative arthritis. Then there were cases in which not only was there pus in the joint, but which were characterized by the very early destruction of the vital joint structures, particularly the cartilage; and these were the ones in which there was definite sepsis and true ankylosis afterward. Now Dr. Cofield's experiences are shared by me. We have both done the same kind of thing, and I think that he agrees with me that not every joint infection can be successfully treated by this method; but we both feel that we have rescued joints from serious and perhaps permanent damage by early intervention of this kind, on the one hand, and, on the other, if a joint by reason of the seriousness of the infection is destined without surgical intervention to be crippled, we feel that the effort to clear the joint of this material does not in any way make the patient's chances for complete recovery worse. Dr. Cotton has shown that joints are more tolerant of infectious processes than we used to believe, and that it is possible for a joint, if given a chance, to overcome grades of infection which we formerly regarded as practically fatal, so far as future usefulness was concerned. But it seems to me that there is a suggestiveness in this effort to save joints in this way which may be of great use in future work; it opens a field for the investigation of the character of the infections, so that if this work is pursued faithfully and with some system, we may before long be able to say, by obtaining fluid, which joints we are going to be able to save by surgical intervention, and in which joints there is no likelihood of this; in which joints it is unnecessary to attack surgically, and in which it is necessary. This is the most important aspect of the work which Dr. Cofield has reported this morning.

Dr. Robert B. Cofield, Cincinnati: I did not want to take the time of this section to go into a detailed case report. Our cases have not been numerous. We probably have had only eight or ten knee joint infections in the last two years in which we felt justified in applying this technic. The important factor is to be able to judge which joint justifies this operation and which will get well with immobilization and treatment. I do believe that in practically all joints that show inflammation and effusion we are justified in aspirating the fluid. It can be done with very little pain to the patient. I have never seen an infection or an increase in inflammation resulting from it if it is done under strict aseptic precautions, and, while the fluid rarely shows any bacterial growth, nor are bacteria visible in the smear, we can tell by the nature of the fluid, the cell count, the great number of polynuclear leukocytes, whether it is a septic joint or not. I think that in all of those cases that show a great increase of polynuclear leukocytes we are justified in opening the joint and following the technic the paper describes. I do not think that we should feel that we should not interfere, because the patient is not going to die from his joint infection. What the patient wants, and what we want, is a good, movable joint. If the inflammation is allowed to go on, the synovia soon suffers, the cartilage degenerates and breaks down and we have a joint that may result in more or less complete ankylosis; therefore, we should not wait until the roentgenogram shows positive changes. It is too late then to expect to get a perfect result. The operation must be done early. It is unfortunate that a great many of the cases we see in the public or general hospital come after there has been destruction of joint structures sufficient to make it impossible to get complete mobilization of the joint afterward. In private practice I have been more fortunate. I have had quite a number of cases showing purulent infection that recovered complete motion in the few months following operation.

As to using an antiseptic in a joint, our experience has not shown that a weak antiseptic, such as I described, is deleterious to the joint structure. Whether it is efficacious or not I am not able to say. As I stated, I prefer to use weak bichlorid, followed by saline, because we have obtained good results from it. In one case of prolonged infection in a child I used ether as advocated by some of the surgeons abroad, and in that case I had the joint open up and discharge pus for a short time, and the result was not so good as in the cases in which I used flushing with weak bichlorid solution. Of course, one case does not prove anything, and this case might not have done so well under the other technic.

As to draining these cases extracapsularly, I think that this will depend a good deal on our judgment as to the invasion of the infection into the periarticular structures. It does not do any harm to put a little silk worm drain or rubber tissue drain in—not into the joint cavity, but into the periarticular structures—and remove it on the third day. This leaves a vent; and if purulent infection is bound to discharge, it will have a free passageway. As Dr. Lord has suggested, in those cases that come to drainage, they should, of course, be placed in the most favorable position.

ORTHOPEDIC OPERATIONS ON THE HAND *

ARTHUR STEINDLER, M.D.
IOWA CITY, IOWA

Unusual as the opportunities are for reconstruction work on the upper extremity, they are counterbalanced by an adequate amount of technical difficulties. To overcome these, investigation, into numerous questions of a theoretical as well as a technical nature becomes necessary.

Some detail work has been devoted to the solution of surgical problems; much less attention has been given to the study of the principles of a mechanical or a physiologic nature. Yet it would seem that mechanical and physiologic analysis is as essential for systematic progress in this field as it is in other fields of surgery.

Conditions existing in the wrist and hand compare favorably with those of the foot and ankle for several reasons: The muscle supply is more abundant; there is, as shall be shown presently, a greater possibility of detaching muscles of the hand and forearm for the purpose of transplantation, by virtue of certain anatomic peculiarities of the tendons; there is also the absence of the influence of gravity and weight bearing; and there are unusual possibilities of improving function by way of muscle reeducation.

I have been attracted to reconstruction work on hands in different orthopedic conditions, for the last two years. A point that struck me early in the work was the necessity of ascertaining and recognizing certain mechanical and dynamic conditions governing the function of the hand and the fingers.

PROBLEM 1. THE POSITION OF DORSAL FLEXION OF THE WRIST

Robert Jones considers this position as a surgical axiom and adds that all injuries of the wrist should be treated in dorsal flexion. The grip of the fingers is diminished if the wrist turns into palmar flexion. We find this point thoroughly substantiated by theoretical considerations as well as by experimental studies. With the wrist in hyperextension, the tonus of the flexor muscles is such that the greatest amount of muscle power can be displayed per unit of contraction. As the wrist goes into the flexion position, the gripping power of the fingers gradually decreases, owing to the gradual loss of tension of the flexors. With the wrist in full flexion and the fingers extended, I have found, as reported on another occasion, that fully three fourths of the potential contractile power of the finger flexors has been exhausted.

It is equally essential and necessary that the wrist joint, once brought into hyperextension, should be

---

* Read before the Section on Orthopedic Surgery at the Sixty-Ninth Annual Session of the American Medical Association, Chicago, June, 1918.

* Owing to lack of space, this article is abbreviated in The Journal by the omission of eight case reports and the illustrations. It will appear in full in the *Transactions* of the section and in the author's reprints.

held there rigidly so as to provide a firm stabilizing position.

As we turn to the anatomic study of the musculature of the wrist, we recognize the latter to be especially designed for this purpose. There are two flexors of the wrist, the flexor carpi ulnaris and radialis; there are three extensors of the wrist: the two extensors carpi radiales and the extensor carpi ulnaris. In addition to this the extensor pollicis and indicis proprius act as accessory extensors of the wrist by virtue of their connection with the second metacarpal.

According to Frohse and Frankel, the volumetric total strength of the extensors of the wrist bears to that of the flexors of the wrist the ratio of 2:1, there being not only a numerical but also a great dynamic preponderance of the extensors over the flexors.

This fact admits of only one interpretation: There exists, first of all, a very considerable amount of muscle power for the purpose of stabilizing the wrist joint by concerted muscle action before the gripping power of the fingers can be displayed to the best advantage. The muscle being unevenly distributed about the wrist, it is obvious that in concerted action equilibrium is obtained only when the power of contraction in the weaker group—the flexors—is increased by hyperextension, and in the stronger group—the extensors of the wrist—is decreased by contraction, so that, in this state of tension the dynamic values of both groups become more equal. And not only is it necessary to carry the wrist into this position of hyperextension, but also one must take care that this position be maintained firmly and with considerable stability, either by muscle action or otherwise.

I have been guided by these considerations when attempting the repair of deformed hands or contracted hands. Clearly the best solution would be if the wrist, after the contraction had been released, could be endowed with sufficient muscle power to be held actively in the desired position. In regard to the transference of power, the muscles of the hand have this decided advantage over some muscles of the foot, that they are not so much bound down by mesotendinous attachments and therefore permit freer exchange and larger displacement. This is true especially of the extensor group, but also of the flexor carpi ulnaris and to some extent of the flexor carpi radialis.

I have no doubt that many cases of flexion contraction or drop hand will lend themselves to the application of tendon transference with favorable result. Such transplantation should be carried out for the benefit of extension power of the wrist in the first place, and the tendons should be anchored accordingly. It is hard to see how a direct transference of muscle power from a flexor muscle to the paralyzed extensors of the fingers can do any practical good unless the extension of the wrist itself is taken care of first.

In many more cases, however, I believe that the muscle power available for transplantation is not sufficient to secure a stabilization of the wrist in the extension position. The situation parallels very much the one in the paralyzed ankle. Here, too, the first mandate of proper function is stabilization, and it is generally found that much better results are obtained by complete stabilization of the ankle than by incomplete and insufficient transference of muscle power. The same principle is applicable to the wrist for the reason that complete stabilization of the wrist in the desired position, even at the exclusion of any motion, is preferable to incomplete motility.

Following are a number of cases in which incomplete motion of the wrist was sacrificed in order to obtain complete stabilization in correct position (five cases).

Case 1.—H. W., man, aged 25, admitted, Jan. 3, 1918, had traumatic paralysis of the musculospiral nerve following a compound fracture of the humerus, seven years before. Contracted drop hand with shrinkage of the extensor muscles of the wrist. Owing to the length of time elapsed and the total waste of muscles involved, no nerve repair work was attempted. Correction of the drop hand was carried out by arthrodesis of the wrist in hyperextension. Following this a tendon transplantation was done. The flexor carpi radialis was turned outward around the radius and united to the extensor carpi radialis longior and brevior. The flexor carpi ulnaris was carried through the interosseous membrane between the radius and ulna and united to the tendon of the common extensors of the fingers. Five weeks after operation, the wrist was rigid in hyperextension. The grip of the fingers was good and improving daily under after-treatment. The transplantation of the flexor carpi ulnaris to the extensor of the fingers secured a fair amount of active extension of the fingers, sufficient for the opening of the fingers.

PROBLEM 2. HYPEREXTENSION CONTRACTION OF THE METACARPOPHALANGEAL JOINT

Extreme flexion of the wrist greatly enhances the occurrence of claw hand deformity. It increases the tension in the extensor muscles and, with the wrist and knuckles as fixed points, the full extensor action is brought forth to produce and to maintain hyperextension in the metacarpophalangeal joints. This position is very difficult to overcome for the finger flexors and lumbricales, as can readily be seen in deformities of Volkmann's ischemic contracture (two cases).

The difficulty of overcoming the hyperextension of the metacarpophalangeal joint is demonstrated by the following case:
